first ulcer after operation. The remaining patient (Case 2) cannot be placed with any certainty in either of these two groups. In the group of patients who had an ulcer preoperatively, it would not be surprising to find recurrences after operation, considering the nature of peptic ulcer. These recurrences would probably have occurred if any other operation had been done instead of splanchnicectomy or even if the splanchnicectomy had been omitted. With the 4 new cases of peptic ulcer this explanation will obviously not apply. These 4 patients averaged 45 years of age at the time of splanchnicectomy and their first ulcer appeared on an average of less than 2 years postoperatively. One is left to speculate as to whether the psychosomatic response of each of these patients had actually changed during this period from a

carried out January 9, 1947

Fig 5 Follow up study, Case 12,

hypertensive pattern to one of altered gastrointestinal function or whether the splanchnic resection itself played the important role by upsetting the balance of the autonomic innervation and establishing a vagal predominance. In 1 instance, however, the patient (Case 12) complained of "sour stomach" each spring for 20 years preoperatively, which would suggest that an ulcer diathesis was already present.

In order to get an idea of the over-all frequency of peptic ulcer preceding splanchnicectomy in this large group of hypertension patients, the records of another 200 cases of splanchnicectomy selected at random were reviewed. This group of 200 patients represented a balanced sample of cases, taken from the various services at University Hospital, who had undergone splanchnicectomy during the period from 1934 to early 1948. It was found that in 3 cases a diagnosis of peptic ulcer was proved, and in another case a presumptive diagnosis of peptic ulcer was

made on the basis of x-ray findings which the patient reported. Four additional patients reported having a past history of vague gastrointestinal symptoms which were somewhat suggestive of peptic ulcer. Since 2 of the latter patients had negative upper gastrointestinal roentgenograms during a symptomatic period and the other 2 gave a very atypical ulcer history, the evaluation of their symptoms will not be attempted. The 4 patients with a definitely demonstrated ulcer would represent 2 per cent of this group of 200 cases. If this percentage is applied to the entire series of 1,498 cases and a correction made for the 8 patients being reported who had a presplanchnicectomy history of peptic ulcer, the incidence of peptic ulcer before operation would approximate $2\frac{1}{2}$ per cent. On the basis of our data it appears that at least 21 per cent of patients with a presplanchnicectomy history of peptic ulcer will develop another ulcer in the early years following the operation. Since these recurrences

Fig 6 Follow up study, Case 12,

carried out January 22, 1947

are most likely to be in a silent form, always threatening a serious complication, it would seem wise to handle these patients with peptic ulcer very cautiously after splanchnicectomy

In both the fatal cases in this series the first ulcer developed following splanchnicectomy, which fact indicates that no individual is free of this threat after operation. The person developing his first ulcer after operation is probably in greater jeopardy because he has had no previous personal experience with peptic ulcer. This factor seems to be the important thing in making patients seek attention when vague signs or symptoms of ulcer do appear, the normal sensations not being present to convince the person of the seriousness of the situation.

COMMENT CONCERNING COMPLICATIONS

Peptic ulcer is so characterized by exacerbations and remissions that we would expect any group of patients with a history of peptic

ulcer to have recurrences and develop occasional complications in subsequent years. However, the rate of complication in this group of patients over a postoperative period which averaged 6 years seems much greater than would have been expected if they had not undergone splanchnicectomy. In the group of 8 patients with a preoperative diagnosis of peptic ulcer (Case 10 is included), there had been 2 episodes of hematemesis and 2 other patients had melena preoperatively. By contrast, postoperatively, these same 8 people had 8 episodes of minor bleeding, 1 perforation, 1 partial obstruction, 2 massive hemorrhages, 1 from a penetrating ulcer. In the group of 4 patients that developed their first peptic ulcer postoperatively, 1 had a questionable episode of melena after 2½ years, another had melena and hematemesis after 18 months, followed by a recurrence at 23 months which necessitated a subtotal gastric resection to relieve the obstruction, and 2 died of severe hemorrhage from a duodenal

carried out April 26, 1947

tain more in the region of the back might be expected with stimulation of these pain receptors (3) According to the segmental distribution of the nervous system, visceral pain from lower portions of the bowel would enter the spinal cord at a lower level and it is more likely that some of their afferents would pass into the lumbar segments of the cord if the lumbar sympathetic ganglia are left intact, pain impulses resulting from spasm of the lower gastrointestinal tract or even from distention could readily reach the cord as either a referred or a direct visceral pain and would be experienced by the patient (4) The possibility of visceral pain from the stomach itself would necessitate a widespread distribution in the cord of the visceral afferent fibers from the stomach. The work of Balhum and Weaver in dogs suggests this as a possibility. They had to section posterior roots of the fourth thoracic through the third lumbar ganglia before they could completely eliminate response to distention of the stomach. If this is also true in humans, then the leaving of the lumbar ganglia undisturbed should permit a certain amount of visceral sensation from the stomach and duodenum to persist.

The comparison of patients who have had splanchnicectomy and lower dorsal ganglionectomy with those who have had a thoracolumbar sympathectomy should help to clarify this point and epigastric pain should be the best indication of this persistence. Jones has shown by balloon distention of various portions of the upper gastrointestinal tract that, as the balloon is successively advanced and redistended, the pain is referred to a point progressively lower in the abdomen, but always somewhere near the midline. When the stomach or the duodenum was distended, sharply localized pain in the midepigastrum was obtained in most cases.

In the examination of the pain noted immediately postoperatively, we find that in only 2 cases was epigastric pain mentioned. It was present on only 1 day in each case, this day being soon after operation on the first postoperative day in Case 4, and on the second postoperative day in Case 10. Oddly enough, both these patients soon had a serious compli-

cation and required immediate laparotomy. One patient (Case 1) complained of epigastric distress during the seventh postoperative day. This was relieved by initial ulcer diet and Sippy tablets. Various abdominal pains are reported, most of these being in the right lower quadrant or right upper quadrant when localization is mentioned. The thing most frequently associated with these pains is distention, and this could probably explain away a good share of the early postoperative pains. The pain could originate in the lower bowel (the portion with afferents to the lumbar segments of the cord) either by distention of this part or pressure on this part by distention in another part of the bowel. Distention, in addition, can cause tugging on adhesions and send painful sensations from the parietal peritoneum. Perhaps the frequent localization in the right upper quadrant and right lower quadrant is due to the presence there of adhesions from old inflammatory processes. From our data it is evident that nausea is not unusual after splanchnicectomy.

In examining the pains mentioned in the later postoperative course of the 8 patients who had abdominal symptoms with their ulcers, it was noted that 5 complained of some kind of vague epigastric sensation, variously described as discomfort, distress, soreness, fullness, pressure, burning or dull ache. Of the other 8 patients, 1 had had a partial gastrectomy (Case 4), 4 made no mention of pain, 1 patient experienced only nausea and vomiting with his ulcer (Case 12), and 1 had a single instance of pain in the abdomen which lasted for several days, 2 months before death. Tenderness of some degree was noted in 4 of the 8 patients with symptoms. In all the patients the typical midepigastric pain of peptic ulcer was absent. However, the presence of a vague type of epigastric distress suggests that some sensation directly from the stomach and duodenum still remained intact. Ulcer management (diet and antacids) effectively eliminated these complaints. Assuming that the stimulation of peripheral nerves and visceral afferents in lower bowel would give a localization other than epigastric there yet remains the vagus. Can visceral sensation reach consciousness by way of the vagus? A study of

abdominal pain present after more extensive resections of the sympathetic nervous system than have been done at this hospital should provide important evidence in answering this question

SUMMARY

In a group of 1498 patients who underwent a splanchnicectomy for hypertension during an 11 year period, there were 13 cases of peptic ulcer following the operation. Three of these had proved ulcers preoperatively, while in 4 a presumptive diagnosis of ulcer was made, and in 3 others symptoms which were suggestive of peptic ulcer were present. Postoperatively an ulcer was demonstrated in 9 cases and a presumptive diagnosis was made in 3 other patients. In 1 instance there were only suggestive symptoms of peptic ulcer both before and after operation and it was not known whether the scarring of the duodenum seen 6 years postoperatively had been present before splanchnicectomy.

Approximately $2\frac{1}{2}$ per cent of the entire group of 1498 patients were considered to have a definite preoperative history of peptic ulcer and 21 per cent of these reported a recurrence following splanchnicectomy.

Preoperatively only 4 patients had a complication of their ulcer. In each case this complication was hemorrhage and it was usually of no great severity. By contrast, 11 of the 12 ulcers which appeared after splanchnicectomy were complicated. It was frequently only by this complication that the ulcer definitely announced its presence. Five of these patients had severe complications, 2 were fatal and the other 3 required emergency laparotomy. One of these was for the closure of a perforation, the other 2 were necessary to ligate arterial bleeders in the base of the ulcer. Of the latter 2 patients, one had an active ulcer at the time of splanchnicectomy and the other probably also had one.

It seems clear that, following splanchnicectomy, frequent and severe complications of peptic ulcer developed in these 12 patients because the normal epigastric pain sensations were either abolished or greatly reduced so that the ulcers were permitted to advance to dangerous proportions without

giving the usual warning. Whether the splanchnicectomy, itself, caused the ulcers or not cannot be concluded from the findings presented, however, 4 patients developed their first ulcer postoperatively and 2 of these resulted in fatal hemorrhages. The patients with the longest history of peptic ulcer before operation usually developed the more serious complications. Patients with recently healed ulcers, and especially patients with active ulcers, developed complications most rapidly after splanchnicectomy, and these complications were among the most severe that were present in this group of patients.

Epigastric pain was present immediately after splanchnicectomy in 2 patients, and in both of these severe complications finally developed. Vague epigastric distress months to years postoperatively was noted by 5 of the 8 patients in whom mention of abdominal symptomatology was made. Severe pain was described by 3 of the patients and this appeared as the ulcer was penetrating or perforating. It is felt that more attention should be paid to vague abdominal signs and symptomatology following splanchnicectomy. Prompt diagnosis and rigid medical management in these cases would reduce the frequency of complication when peptic ulcer is present.

SIGNIFICANCE OF AN ULCERATING LESION IN THE STOMACH FOLLOWING GASTROENTEROSTOMY

WARD K. GRAY, M.D., F.A.C.S., and KARL A. LOFGREN, M.D., Rochester, Minnesota

THE development of an ulcerating lesion in the stomach after gastroenterostomy is not uncommon, and yet we have been unable to find any reports in the medical literature in which such lesions have been discussed. For this reason and because we had the distinct impression that the incidence of malignancy was high for gastric cancer that developed after gastroenterostomy, it seemed worth while to review in detail these cases at the Mayo Clinic during the ten-year period from January 1, 1938, through December 31, 1947, in which a gastric lesion requiring surgical intervention developed subsequent to gastroenterostomy for duodenal ulcer.

This series of patients does not include every patient in whom a gastric lesion was demonstrated after gastroenterostomy, for many patients were seen at the clinic during this period who declined operation, who were operated on frequently elsewhere or who were treated conservatively. This study does include all patients in whom a demonstrable gastric cancer followed gastroenterostomy and who went through surgical treatment, including distal gastrectomy or partial gastrectomy. It has been accepted generally that the coexistence of an active duodenal ulcer and a gastric cancer is very rare. The high gastric acidity and the increased peptic activity that is associated with an active duodenal ulcer tend to prohibit or delay the development of a malignant neoplasm in the stomach, as suggested by Wilbur and Rivers. Bockus has stated that "patients with this disease (duodenal ulcer) are much less likely to develop cancer of the stomach than those who have no such disease whatever." Eusterman and others have expressed the opinion that "the incidence of duodenal ulcer is in a certain sense

an insurance against carcinoma of the stomach." They reported that of 15,985 patients who underwent roentgenologic examination of the stomach for digestive disturbance, 2,047 (12.8 per cent) demonstrated deformities of the duodenal cap which were characteristic of duodenal ulcer, 167 (1 per cent) had roentgenologic evidence of gastric ulcer, 24 (0.15 per cent) showed evidence of both duodenal and gastric ulcer, and in none was there evidence of a duodenal ulcer which was associated with what was apparently a malignant lesion in the stomach.

In 9,171 consecutive postmortem examinations at the Cook County Hospital, Portis and Jaffé found 240 benign gastric ulcers, 215 duodenal ulcers, 19 benign gastric ulcers associated with a duodenal ulcer, but in no patient did they find a duodenal ulcer associated with a gastric carcinoma. Smithies and Ochsner, however, have reported on 12 patients in whom gastric cancer was coexistent with benign peptic ulcer, in 8 of whom the peptic ulcer was located in the duodenum. Wilbur and Rivers in 1932 reported on 33 patients who had duodenal ulcer associated with gastric cancer. Four of these patients had undergone a previous gastroenterostomy for duodenal ulcer. In 20 of the 33 patients the gastric lesion was a malignant ulcer, whereas in the remaining 13 patients a massive gastric carcinoma was found. In all of the 33 patients the nature of the lesion was proved at operation or necropsy.

Fischer, Clagett, and McDonald found records of only 48 cases of coexistent duodenal ulcer and gastric cancer in the surgical and postmortem files of the Mayo Clinic from 1911 through 1944. In only 1 of those 48 patients had a previous gastroenterostomy been made for duodenal ulcer. During this same period of 34 years, there were approximately 600 instances in which a coexistent duodenal and a benign gastric ulcer were seen on roentgeno-

the Division of Surgery, Mayo Clinic and Mayo Found-

logic examination at the clinic. The association of a duodenal ulcer and a benign gastric ulcer appears therefore to be about 12 times as common as the association of a duodenal ulcer and a gastric carcinoma (a ratio of 600.48 in approximately 45,000 patients).

There were 825 patients seen at the clinic during the 10 year period between January 1, 1938, and December 31, 1947, in whom a previously established gastroenteric stoma for duodenal or gastric ulcer had to be discontinued owing to subsequent complications and for whom a partial gastrectomy was carried out as a secondary procedure. These subsequent complications which followed the original gastroenterostomy and for which surgical treatment was advised included jejunal ulceration near the gastroenteric stoma, malfunctioning gastroenteric stoma, gastric ulcer and gastric carcinoma, listed in order of their incidence. In Table I may be seen the relative incidence of benign and malignant lesions in this series of patients.

Forty-one gastric lesions developed after a gastroenterostomy for duodenal ulcer, of which 11 (27 per cent) were gastric cancers and 30 (73 per cent) were benign gastric ulcers. The

association of an old duodenal ulcer with subsequent gastric cancer in a stomach that has undergone gastroenterostomy appears to be more common perhaps than one would think in view of the few cases on record in which this association has been found in routine studies of patients not subjected to previous gastric operations. Of 11 gastric lesions that developed or were retained after a gastroenterostomy for gastric ulcer, 6 (55 per cent) were proved to be malignant and 5 (45 per cent) were proved to be a benign gastric ulcer at the time of the subsequent gastric resection. Included in this study was 1 patient in whom a gastroenteric stoma had been made elsewhere for no demonstrable ulcer and in whom a gastric carcinoma that required surgical intervention developed several years later.

In the routine study of patients who are examined roentgenologically on account of gastric complaints, the ratio of gastric ulcer to gastric carcinoma has been found to be about 13 at the clinic (2). In our small series of 53 patients in whom a previous gastroenteric stoma had been made for duodenal or gastric ulcers (in all instances except 1), the ratio of gastric ulcer to gastric cancer is almost reversed, being 21 (35.18). It appears that a patient with an ulcer diathesis is less likely to have gastric carcinoma.

GASTRIC LESIONS THAT FOLLOWED GASTROENTEROSTOMY FOR DUODENAL ULCER

Of the 41 patients in this group 30 had benign gastric ulcers and 11 had gastric cancers that followed previous gastroenterostomy for duodenal ulcer.

Of the 30 patients in whom benign gastric ulcers developed, 12 had undergone gastroenterostomy at the clinic. The average age of these patients at the time of gastroenterostomy was 39.3 years and at the time of the subsequent gastric resection 52.3 years, thus giving an average time interval of 13.0 years between these 2 operations.

Of the 11 patients in whom carcinoma developed, 2 had undergone gastroenterostomy at the clinic. The average age of these patients at the first operation was 35.9 years and at the second 50.9 years, an average time interval of 15.0 years between these 2 operations.

Symptoms In the group with benign gastric lesions, all patients complained of distress which was characteristic of peptic ulcer. In the group with malignant gastric lesions, 5 of the 11 patients gave a definite history which strongly suggested peptic ulcer, 2 presented a less clear-cut history, 1 gave no characteristic story, and 3, on the other hand, presented a history pointing toward malignancy, that is, anorexia, progressive weakness, loss of weight and so forth. The average loss was 8.5 pounds (3.8 kgm) for the patients with benign lesions and 16.5 pounds (7.5 kgm) for those with malignant lesions.

Clinical findings The value of free hydrochloric acid in the gastric contents averaged 25.6 units in the patient with benign lesions. It was absent in 3 (10 per cent) of this group, but 1 patient had a gastrojejunocolic fistula and another had a gastroileac stoma, which had been made elsewhere, so that the apparent achlorhydria could be accounted for in 2 of the 3 patients. The value for free hydrochloric acid averaged only 9 units for the 8 patients with malignant lesions for whom it was determined, and free acid was entirely absent in 4 (50 per cent). The quantity of hemoglobin averaged 12.6 grams per 100 cubic centimeters of blood for patients with benign lesions and 11.8 grams for those with malignant lesions.

Roentgenologic findings In the group of patients with benign lesions the roentgenographic diagnosis was "gastric ulcer" in 20 (67 per cent), "gastroenteric stoma free" in 6, "gastrojejunocolic fistula" in 2, "obstruction" in 1, and no examination was done in 1 who was bleeding. In patients with malignant lesions the roentgenographic diagnosis was "carcinoma" in 5 (45 per cent), "ulcerating lesion" in 4, "gastrojejunitis" in 1, and "obstruction" in 1.

Comment The benignancy of the gastric lesion was suggested frequently by the patient's symptoms and by the clinical findings, a gastric carcinoma was concealed and was revealed only at the time of operation. The clinical diagnosis was difficult in those patients who harbored malignant lesions of the stomach in the presence of an old gastroenteric stoma and an old duodenal ulcer. In 2 of these patients the preoperative clinical impression was "gas-

tric ulcer," in 2 "malfunctioning gastroenteric stoma," and in 3 "stomach ulcer," but at operation they were all found to have carcinoma of the stomach. The 3 case reports which follow illustrate how frequently a malignant gastric lesion in a stomach that has undergone gastroenterostomy can simulate a benign condition.

"Gastric ulcer" was the clinical impression in the following 2 patients in whom a malignant gastric lesion was found at operation.

A male, aged 36 years, gave a history of epigastric pain and vomiting for 1 year. Thirteen years previously he had undergone gastroenterostomy elsewhere for duodenal ulcer. The roentgenographic examination revealed an "ulcer on the lesser curvature below the angle, associated with diffuse gastritis." The free hydrochloric acid in the gastric contents measured 38 units, and the total acids measured 48 units after the usual test meal. At operation a scirrhous, colloid, grade 4 adenocarcinoma (Broders' method), arising on the lesser curvature 3 centimeters above the pylorus, was found. The tumor, which measured 7 by 5 by 2 centimeters, already had invaded the serosa and regional lymph nodes of the stomach. A partial gastrectomy was carried out, but the patient survived only 6 months after operation. The carcinoma was 5 to 6 centimeters from the gastroenteric stoma (Fig. 1).

A male, aged 56 years, had a gastroenterostomy performed for a subacute perforating duodenal ulcer 29 years previously at the clinic. Symptoms referable to the stomach had recurred only 1 month prior to his present admission and consisted of diffuse upper abdominal and lower thoracic pain associated with some fatigue. The diagnosis, by means of roentgenography, was "large ulcer on the lesser curvature, just below the angle, associated with extensive gastritis." The quantity of free and total acids in the gastric contents was not determined. A rigid regimen of medical management was instituted in the hospital and within 11 days his subjective symptoms had disappeared. Surgical treatment was advised, however, and at operation an extensive, grade 4 colloid adenocarcinoma, involving the lesser curvature with spread to the serosa and regional lymph nodes, was found. The lesion was of the linitis plastica type and demonstrated only a small area of mucosal ulceration. The patient died 12 months after a partial gastrectomy was done.

"Stomal ulcer" was the clinical impression in the following patient who was found to have a malignant lesion at operation.

A male, aged 40 years, had had a gastroenterostomy for duodenal ulcer 22 years previously. Symptoms referable to the stomach, consisting of high abdominal distress which was consistent with peptic

TABLE II—PATHOLOGY OF CARCINOMA OF STOMACH FOLLOWING GASTROENTEROSTOMY FOR DUODENAL ULCER

			7 grade 4	8-C

*Thought to be a benign ulcer at operation

ulcer, had recurred 9 years prior to his present admission, and during the last 4 years his pain had become gradually more severe. He had lost 20 pounds (9.1 kgm). The quantity of free hydrochloric acid in the gastric contents was not determined but roentgenographic examination revealed an "ulcer high on the lesser curvature of the stomach, associated with extensive hypertrophic gastritis." At operation a grade 4 ulcerating, mucous adenocarcinoma was found on the lesser curvature near the angle. It was a superficial lesion, measuring 5 by 5 by 0.5 centimeter and fortunately the serosa and regional lymph nodes showed no evidence of invasion. The carcinoma was about 4 centimeters above the gastroenteric stoma (Fig. 2).

Pathologic features In the group of patients with benign lesions, the ulcers averaged 1.5 to 2.0 centimeters in diameter and none measured over 3.5 centimeters. A microscopic diagnosis of benign gastric ulcer was made in each instance. All the old duodenal ulcers were either healed or entirely inactive at the time of the second operation.

Of the 11 patients with malignant lesions, 5 had gross ulcerating lesions, 3 had massive carcinomas, 2 had diffuse carcinomas of the linitis plastica type with involvement of the entire thickness of the gastric wall, and 1 had a polypoid carcinoma (Table II). Most of these lesions were of high grade (Broders'

classification) and 7 (64 per cent) were classified as grade 4 carcinomas. Invasion of the serosa and regional lymph nodes had occurred in 8 (73 per cent). It is interesting to note that of the 5 malignant ulcers, 4 measured 5 centimeters or less in diameter. One of these was thought to be a benign gastric ulcer until it was examined microscopically by the pathologists and found to be a superficial mucous adenocarcinoma, grade 4.

GASTRIC LESIONS THAT FOLLOWED GASTROENTEROSTOMY FOR GASTRIC ULCER

Of the 11 patients in whom gastric lesions developed after gastroenterostomy for gastric ulcer, in 5 the lesions were benign gastric ulcers, but in 6 they were malignant neoplasms.

Of the 5 patients in whom a benign gastric ulcer was found, 2 had had a previous gastroenterostomy at the clinic. In these 2 and in 1 other patient, local excision of the gastric ulcer was carried out concurrently with the gastroenterostomy. The average age of the patients at the time of the second operation was 57.8 years. The average time interval subsequent to the gastroenterostomy was 17.0 years.

Of the 6 patients in whom a malignant neoplasm was found, 2 had had their gastroenterostomy at the clinic. The average age of the patients at the time of gastrectomy was 51.0 years, and the average time interval between the gastroenterostomy and the second operation was only 6.0 years. In 5 patients this time interval was 2 years or less. It is significant to note that in no instance was a biopsy or local excision of the gastric ulcer done in this group at the same time that gastroenterostomy was performed.

Symptoms Of the 5 patients who had a benign gastric ulcer, all gave a history that was quite characteristic of peptic ulcer, but of the 6 patients who had a malignant lesion, only 3 gave a history suggesting peptic ulcer, whereas 1 gave a less definite history of ulcer and 2 gave a history which was not suggestive of peptic ulcer. The average loss of weight prior to admission to the clinic was 9.8 pounds (4.4 kgm) for the patients with benign lesions and 22.5 pounds (10.2 kgm) for those with malignant lesions.

Fig 1 Ulcerating grade 4 mucus producing adenocarcinoma on the lesser curvature of the stomach. A gastroenteric stoma for duodenal ulcer had been made 13 years previously

Fig 2 Superficial grade 4 ulcerating mucous adenocarcinoma on the lesser curvature and posterior wall of the stomach. A gastroenteric stoma for duodenal ulcer had been made 22 years previously

Clinical findings The quantity of free hydrochloric acid in the gastric contents ranged from 26 to 50 units in the group of patients with benign ulcers. It was also present in 3 of the 6 patients with gastric cancer, the quantity ranging from 14 to 36 units.

Roentgenologic findings In the 5 patients with benign lesions, the roentgenographic diagnosis was "gastric ulcer" in 4 and "deformity" of the gastric wall in the remaining 1, who actually had scarring of the wall from a previously excised gastric ulcer. In the 6 patients with malignant lesions, the diagnosis was "carcinoma" in 3, "ulcerating lesion" in 2, and "obstruction" in 1.

Comment The gastric lesion for which the gastroenterostomy had been done apparently had failed to heal in the majority of these patients for 7 of the 11 patients required further surgical treatment within 4 years after their gastroenterostomy for gastric ulcer. This is particularly important in the case of the 6 patients who harbored a malignant process at the second operation. The true nature of the neoplasm evidently had not been recognized at the time of the gastroenterostomy in the 5 patients who, within 2 years following the first operation, had gastric resections for carcinoma. A biopsy for the purpose of establishing a microscopic diagnosis would have been

of immense value at the time of the gastroenterostomy and probably would have altered the surgical attack at the earlier and more favorable period. The following case report illustrates the point, although this patient was more fortunate in the outcome than are many others.

A male, aged 62 years, had undergone exploration at the clinic 1 year previously for an ulcer high on the posterior wall of the stomach, just below the insertion of the esophagus. The ulcer was about 2.5 centimeters in diameter. A posterior gastroenterostomy was carried out because a direct attack seemed impossible on account of the inaccessible position of the lesion and the large number of adhesions already present from a previous laparotomy.

The patient returned to the clinic 1 year later because of symptoms referable to the stomach. These consisted of persistent bloating and epigastric distress. The free hydrochloric acid in the gastric contents measured 36 units and the total acids 52 units after the usual test meal. Roentgenographic examination again demonstrated the gastric ulcer, though it appeared to be smaller in size after the gastroenterostomy. Operation was advised and approximately four-fifths of the stomach was resected. A superficial colloid carcinoma on the posterior wall of the stomach just distal to the insertion of the esophagus was encountered. The lesion had not invaded the serosa nor the regional lymph nodes. The patient soon returned home and progressed well from the standpoint of the stomach for 5 years when he died from some cause which could not be determined in our follow up.

TABLE III — PATHOLOGY OF CARCINOMA OF STOMACH FOLLOWING GASTROENTEROSTOMY FOR DUODENAL ULCER

Gross description	Number	Size cm	Grade (Broders)	Type (Dukes)
Ulcer type	3	5 cm in diameter*	4	B
		3x2x0.5*	3	B
		3x1x2*	—	A
Massive cancer	3	7x5x2	4	C
		7x6x4	2	C
		Large	4	C
Total	6		2 grade	1 A
			1 grade 3	2 B
			3 grade 4	3 C

*Thought to be a benign ulcer at operation

Pathologic features Of the 6 malignant lesions in this group, 3 were malignant ulcers but all were thought to be benign gastric ulcers until they were examined microscopically by the pathologist (Table III). One of these patients had also an associated smaller benign gastric ulcer, 0.5 centimeter in diameter, about 6 centimeters distal to the malignant ulcer on the lesser curvature. Three were grade 4 lesions (Broders' classification) and the serosa and regional lymph nodes had been invaded in 3 instances.

GASTRIC LESIONS THAT FOLLOWED GASTROENTEROSTOMY FOR OTHER REASONS

One patient was included in this study because she had a gastric cancer that followed gastroenterostomy that had been done 23 years previously for some indeterminate lesion.

A female, aged 65 years, had complained of daily intractable epigastric distress since gastroenterostomy had been made. The first impression of the clinicians on her admission to the clinic was that her complaints were functional in nature but with further study operation was advised because of her history of persistent symptoms and because the roentgenographic diagnosis of probable jejunal ulcer and jejunitis. An extensive, diffuse grade 4 small cell adenocarcinoma involving the lower half of the stomach and first portion of the duodenum was found. It had invaded the serosa and regional lymph nodes. The lesion was of the linitis plastica type and was associated with marked inflammatory reaction in the gastric wall as well as around the gastroenteric stoma. A partial gastrectomy

was carried out. The patient, however, succumbed 4 weeks later from complications, probably peritonitis.

SUMMARY AND CONCLUSIONS

A review of data on 53 patients in whom lesions in the stomach developed after gastroenterostomy has confirmed the impression of the authors that such lesions will show a high incidence of malignancy. Eighteen (34 per cent) of the 53 patients in this series had malignant lesions of the stomach requiring subsequent gastric resection. Of the 53 gastroenteric stomas, 41 had been made on account of duodenal ulcer, 11 on account of gastric ulcer and 1 for other reasons.

Eleven of the 41 patients who had gastroenterostomy for duodenal ulcer experienced malignant lesions of the stomach, as demonstrated subsequently at the time of operation. It has been found to be extremely difficult to determine clinically the true nature of a lesion in a stomach that has undergone gastroenterostomy. The clinical history and findings may mask the real nature of such a lesion and give the impression that a malignant neoplasm is benign. Five of the 11 patients in whom carcinoma of the stomach developed gave a history that was quite characteristic of peptic ulcer, and in 4 of these 11 patients appreciable quantities of free hydrochloric acid were found in the gastric contents.

Six of the 11 patients who had had a gastroenteric stoma made for gastric ulcer were found to have malignant lesions of the stomach which either had gone unrecognized at the time of gastroenterostomy or had developed later. At operation some of these malignant lesions appeared to be benign grossly. Gastroenterostomy alone without local excision or biopsy of the gastric ulcer was done in 8 persons, in 6 of whom malignant gastric lesions were found at the time of operation. A biopsy or local excision of the gastric ulcer at the time of the original operation would have been of immense value and might have changed the surgical attack to a more radical one.

The roentgenographic examination of a lesion in the stomach following gastroenterostomy has been found to be more than usually difficult owing to the marked structural

changes, inflammatory conditions and obstructive features that are so often encountered. An accurate roentgenographic diagnosis has been found to be almost impossible when the new lesion has developed in the portion of the stomach distal to the old gastroenteric stoma.

In view of the high incidence of malignancy in the ulcerating lesions of the stomach following gastroenterostomy, the importance of suspecting and ruling out carcinoma before any conservative management is instituted cannot be emphasized too strongly.

ANALYSIS OF POSTOPERATIVE CHOLANGIOGRAMS

JULIAN A STERLING, M D, M Sc (Med), PAUL S FRIEDMAN, M D,
VINCENT P RAVEL, M D, and LEON SOLIS-COHEN, M D, Philadelphia, Pennsylvania

THERE is a lack of precision in descriptions of the common bile duct. In an effort to clarify this subject we have analyzed delayed, or indirect, cholangiograms (6, 20, 21, 26). These studies have been supplemented by clinical and post-mortem observations.

METHOD

The cholangiograms were made of patients 5 or more days postoperative by the injection of contrast substances into a tube indwelling in the biliary tract. Cholangiography was usually performed 3 hours after the midday meal. Fifteen minutes before examination the patient was given a sublingual dose of nitroglycerine (0.006 mgm).

Twenty cubic centimeters of diodrast was warmed to body temperature in a syringe fitted with a No. 21 gauge needle. All air bubbles were eliminated. The hypodermic needle was inserted into the external limb of the tube as close to the abdominal wall as conveniently possible and a (curved) hemostat clamped across the needle and tubing to create a fluid tight junction.

Two to 5 cubic centimeters of diodrast were injected into the tubing under fluoroscopic observation. After 20 to 40 seconds, an additional 2 to 10 cubic centimeters were injected. During and after this observation period, localized roentgenoscopic films were made, so that at least 2 anteroposterior and 1 right lateral 10 by 12 film exposures were made, with the Bucky diaphragm and with 100 milliampere tube current. More diodrast was injected if necessary. In some cases, re-examination was done after 30 minutes while the external limb of the indwelling tube was

clamped. After completion of radiographic studies, the tube was irrigated with normal saline solution.

Injection studies were performed upon fresh autopsy specimens after removal of the duodenum, hepatic pedicle, and the adjacent pancreas. The proximal and distal openings of the duodenum were ligated, or clamped. In some instances, air was injected into the duodenal canal in order to overcome serosal agglutination and to separate mucosal folds. The pancreatic and common bile ducts were identified and cannulated at an adequate distance from the duodenal wall. Ureteral catheters or metal needles were tied into place. Five to 15 cubic centimeters of diodrast or iodochlorol were injected into each duct and roentgenograms were made.

OBSERVATIONS

A total of 50 cholangiograms on 41 patients was reviewed. In this series of cholangiograms there was no mortality due to the examination. The procedure was complicated in only 2 cases, and in those by clinical symptoms of pancreatitis which appeared for 2 to 4 days following cholangiography. Three patients who died subsequently in the hospital were autopsied. One died because of a stone impacted in the common bile duct, 1 because of myocardial failure and hepatocellular disease, and 1 as a result of hemorrhage from the hepatic artery into the common bile duct (31).

The normal cholangiogram. Under fluoroscopic observation the contrast media injected through the T tube normally entered the common bile duct and duodenum without delay or obstruction. The origin of the common bile duct was estimated to be in the right half of the median sagittal plane of the body at approximately the twelfth thoracic intervertebral space. The capacity of the normal common duct varied from 5 to 10

Condensed from thesis submitted by Dr J. A. Sterling in partial completion of requirements for degree of M. Sc. (Med.) in Surgery to the Faculty of the University of Pennsylvania.

From the Departments of Surgery and Radiology of the Jewish Hospital Philadelphia, Pennsylvania.

cubic centimeters Fluoroscopically and roentgenographically (Fig 1) in the anteroposterior plane, the contrast substance was seen to follow a continuously curving course. It first was curved slightly medially, then it passed laterally and nearly parallel to the midline. As the duct terminated there was a sharp change in direction with angulation toward the right lateral abdominal wall and a concomitant decrease in the diameter of the common duct.

On lateral view, a flat double curve was seen in the course of the common duct which was in the ventral vertical plane. At first the common duct curved anteriorly, then, inferiorly and posteriorly to the level of the duodenum. In this area it usually overlaid the vertical axis of the anterior border of the vertebral column. The common duct finally coursed slightly anteriorly and inferiorly to end within the duodenal canal.

In 50 cholangiograms the widest diameter of the common bile duct varied from 4 to 23 millimeters, averaging 11 millimeters. Including 25 instances in which definite abnormalities of the common bile duct existed it was found that the diameter of the normal common bile duct varied from 4 to 10 millimeters, with an average of 7 millimeters.

A decrease in diameter of the terminal segment of the extraduodenal common bile duct, associated with a straightening of the duct wall was found in 16 patients. The narrowed segment measured from 4 to 18 millimeters in length (mean and average was 10 millimeters). This narrowed portion probably represented the transpancreatic portion of the extraduodenal common bile duct.

The transduodenal segment of the common duct was visualized on 42 cholangiograms. Of these, 21 were considered to be normal in appearance. The duct terminated at approximately the level of the second lumbar transverse process in the majority of cases, and varied from levels of the first to the third transverse processes. The average length of the transduodenal segment ("papilla") of the common bile duct was found to be 14 millimeters (32).

The lumen of the common bile duct decreased in diameter as it crossed the duo-

Fig 1 Normal cholangiogram made after injection of diodrast into the T tube. Diodrast entered the duodenum without delay. There is a medial convexity to the extraduodenal common bile duct. The distal segment of the common duct is seen to taper slowly in diameter to empty into the medial aspect of the descending portion of the duodenum, at approximately the level of the transverse process of the third lumbar vertebra.

denal wall. Its sides presented a double concavity, or scalloping, which gave the lumen of the duct the appearance of a funnel. The duct finally terminated as a thin filamentous canal. The terminal orifice of the common bile duct measured 1 millimeter or less in diameter in 16 cases, between 1 and 2 millimeters in 25 cases, and was 4 millimeters in diameter in 1 case. Normally the duodenal canal filled rapidly above and below the terminal orifice of the common bile duct.

The transduodenal (pars intestinalis) segment of the common bile duct was seen most clearly on injected fresh postmortem specimens (Fig 2a). The lumen appeared as a curving funnel which gradually decreased to a filamentous channel. The axis of the transduodenal segment entered the duodenal wall at slightly less than a right angle and usually traversed the greater portion of the duodenal wall parallel to the axis of the duodenal canal. As it terminated, the common bile duct

Fig 2 a, *Cholelithogram* made after injection of common bile duct with diodrast through catheter. The terminal portion of the common duct is seen as a tapering continuously curving funnel, ending as a filamentous channel. b, *Pancreatic ductogram* made after injection of common bile duct with diodrast and of pancreatic duct with lipiodol. The common duct is visualized as in a. The lipiodol has diffused through the pancreatic ductal system. Some of the oil has emptied into the duodenum through a small separate orifice, adjacent to the termination of the common bile duct.

turned to empty into the duodenal lumen at approximately a right angle to the duodenal axis.

On the pancreatic ductogram (Fig 2b), the pancreatic duct was seen as a gently curving arc which approached the termination of the common bile duct to empty into the duodenal canal after an acute bend in its axis toward the orifice of the common bile duct. Separate orifices for pancreatic and common bile ducts were usually visualized.

The abnormal cholangiogram. Abnormalities were observed in 25 of the 50 cholangiograms. These were choledocholithiasis, 12 cases, spasm, 6 cases, reflux into pancreatic duct, 4 cases, stricture of common bile duct, 3 cases.

Fluoroscopic observation revealed 17 instances in which there was delay in the entrance of the dye into the duodenum. This was due to (a) residual calculi within the common duct and an irregular transduodenal

segment in 13 cases, (b) to spasm associated with dyskinesia in 3 cases, and (c) to an artificial choledochoduodenostomy in 1 case.

Choledocholithiasis. When injected through the external limb of the T tube in patients with choledocholithiasis, diodrast entered the duodenum sluggishly. The capacity of the duct was 15 to 25 cubic centimeters. The common bile, common hepatic, and frequently the hepatic ducts were dilated. Calculi appeared as radiolucent defects. They were usually circular, crescentic or irregular in contour. Stones were most frequently impacted at the termination of the extra-duodenal course of the common bile duct (Fig 3). Diodrast, which passed beyond a calculus, filled the tapering filamentous lumen of the termination of the "pars intestinalis" of the common bile duct.

In 1 instance reflux was seen from the common bile duct to the pancreatic duct simultaneously with the impaction of a stone

in the common bile duct (Fig 3) In this case, the site of the stone impaction was 1 centimeter proximal to the location of the reflux

It was important to distinguish artefacts, such as air bubbles, from calculi The former were typically inconstant in location and were not faceted Congenital folds in the mucous membrane of the duct wall were also confusing

Spasm In patients with active spasm of the sphincter of Oddi, diodrast was injected into the external limb of the T tube against resistance It entered the duodenum as a slow trickle However, free flow into the duodenum commonly occurred at some time during the cholangiography The injection was usually painful, although pain was relieved when the duct emptied The capacity of the common bile duct was 15 to 20 cubic centimeters in these patients with spasm On the roentgenogram there was increased angulation between the extraduodenal and transduodenal segments of the common bile duct At its termination the lumen of the common bile duct tapered rapidly to a narrow filament, usually more irregular and longer than normal

Reflux into pancreatic duct In most patients who were found to have reflux from the common duct into the pancreatic duct, diodrast injected in the external limb of the T tube entered the duodenum almost immediately During the interval between additional injections of diodrast it was observed that the terminal portion of the pancreatic duct was filled with contrast media from the common bile duct (Fig 4a) In other cases, the pancreatic duct was partially filled before the contrast medium was seen in the duodenum (Fig 4b) The length of the common channel for pancreatic and common bile ducts varied from 2 to 10 millimeters At its termination, the lumen of the common channel measured from 1 to 2 millimeters in diameter

Clinical pancreatitis was present (31) in 1 of the 4 patients with reflux (Fig 4a) Signs and symptoms of transient pancreatitis appeared after cholangiography in 1 patient who had reflux, and in 1 patient without re-

Fig 3 *Choledocholithiasis and reflux* Cholangiogram made after injection of diodrast into the T tube The contrast medium entered the duodenum very sluggishly and was injected against marked resistance The biliary ducts are dilated The pars intestinalis of the common bile duct is seen as an S shaped filamentous termination in the medial aspect of the descending duodenum The terminal portion of the pancreatic duct is visualized adjacent to the pars intestinalis through reflux from the common bile duct A circular shadow of a calculus is impacted in the distal portion of the extraduodenal common bile duct, proximal to the site for reflux into the pancreatic duct This stone disappeared after Pnbraam therapy

flux Another patient who presented reflux on one examination did not present it on subsequent studies

Stricture In the presence of a complete stricture of the common duct, diodrast injected through the external limb of the T tube entered the common bile duct against marked resistance Diodrast did not enter the duodenum, the hepatic radicles were markedly dilated and reflux of contrast medium occurred along the T tube

In these cases with stricture the content of the biliary tree was 25 to 35 cubic centimeters The diameter of the lumen of the common bile duct was greater than 18 millimeters The distal portion of the common bile duct was distorted and blunted with con-

Fig 4 a, *Reflux (CM)* Roentgenogram made after injection of diodrast into the T tube. The diodrast entered the duodenum without obstruction. The proximal segment of the common duct is displaced laterally because of extrinsic pressure from a pseudocyst of the pancreas. The distal segment of the common bile duct ends as an S shaped curve terminating in the medial portion of the descending duodenum at the level of the third lumbar transverse process. There is slight diminution in the caliber of the common bile duct; the terminal portion of the pancreatic duct appears of equal or greater diameter than the bile duct in the area of the *pars intestinalis*. The distal centimeter of the pancreatic duct is visualized, as well as 7 to 8 millimeters of the common channel present in this case for the common bile and pancreatic ducts. Duodenal canal filled prior to demonstration of reflux. b, *Reflux (LC)* Roentgenograph taken after injection of diodrast into the T tube. The course and diameter of the common duct are normal. The termination (*pars intestinalis*) of the common duct cannot be clearly identified. At the papilla the termination of the pancreatic duct and approximately 1 centimeter of its distal course is visualized. Pancreatic duct reflux occurred just prior to appearance of contrast medium in the duodenal canal. Diodrast entered the duodenum rapidly. A cholangiogram repeated 10 days later revealed no evidence of reflux. The patient has been asymptomatic for 2 years.

velocity directed caudad. Diodrast was not visualized in the transpancreatic or transduodenal portions of the common bile duct.

DISCUSSION

Routine cholangiography in patients following common duct operations has increased knowledge of the physiology and anatomy of the common bile duct and their surgical significance (5, 6, 7, 10, 11, 13, 15, 22).

However, a lack of uniform terminology exists as well as an inadequate description of the normal and abnormal common bile duct (8, 10, 14, 27, 28). The major deficiencies are (a) insufficient description of the fluoroscopic findings, (b) lack of existing standards for measurement of the common duct diameter, (c) insufficient description of

the details and character of the termination of the duct, and (d) incomplete definition as to the location of the duct and its divisions.

In addition, reference is made in the literature to the "ampulla" and the "papilla" of Vater as if they were interchangeable terms. However, the "ampulla," as a "dilatation" exists only in the early embryo as a result of the merging of the hepatopancreatic duct with the duodenal canal and rapidly recedes to nonexistence (3, 8, 12, 29). The "papilla," or "swelling" is a definite portion of the termination of the common duct in the adult (12). It represents an increase in tissues comprising a sphincter-like mechanism identified by Oddi (23). It, most likely, originates in the mesenchymal structures peculiar to the common duct tissues (8, 29).

The common bile duct may be divided into extraduodenal and transduodenal segments. The transduodenal segment is equivalent to the "papilla" or the "pars intestinalis" (8, 12). The extraduodenal segment, in certain instances, may present a transpancreatic portion (7, 27). These divisions of the common bile duct can be identified, on roentgenography, by the injection of a contrast medium into the common duct.

The common bile duct presents a constantly curving axis in both anteroposterior and lateral planes. Straightening of its course may indicate an abnormality due to extrinsic pressure (Fig 4a). In the distal portion of the extraduodenal common bile duct, however, straightening of the duct may indicate that its course is transpancreatic. The course and direction of the common bile duct depends upon the anatomical disposition of adjacent viscera, but can usually be predicted in the normal individual.

Roentgenographically, the common bile duct presents its widest diameter distal to the junction of the cystic and hepatic ducts and proximal to the transpancreatic segment. The average diameter of the widest part of the normal common bile duct on the cholangiogram is 6.9 millimeters. Measurement of the same segment of the choledochus in fixed and fresh anatomical specimens indicates an average diameter of 6.3 millimeters in the normal adult (32). In these studies, the duct is abnormal when its diameter is greater than 1 centimeter.

The transduodenal segment of the common bile duct may be identified by its change in direction, and its funnel shape, as its lumen decreases in size to terminate in a filamentous canal. Frequently, this segment of the duct cannot be visualized on roentgenography. Its patency must then be inferred by the presence of sufficient contrast medium in the duodenum. Fluoroscopic observation may reveal a correlation between symptoms of biliary dyskinesia and the existence of spasm in the transduodenal segment of the common bile duct.

In this series there are 4 instances (8 per cent) of reflux from the common bile duct into the pancreatic duct. In only 2 of these

are the findings persistent, since subsequent examinations in the others did not demonstrate diodrast in the pancreatic duct. This observation contributes support to Archibald's theory (1, 2) that sphincteric muscle action at the papilla is segmental and intermittent in character and that reflux into the pancreatic duct can occur when the most distal segment of the sphincter is active. The relationship between reflux and pancreatitis (11, 13, 19, 24, 25) cannot be demonstrated in this series, since pancreatitis occurs both with and without evidence of reflux and since reflux occurs both before and after diodrast enters the duodenum from the common duct. It has been observed that papillary sphincterotomy may be indicated for relief of symptoms caused by reflux occurring into the pancreatic duct before the common duct empties into the duodenum (13).

It is of extreme interest to note that calculi are impacted at the distal portion of the extraduodenal segment of the common bile duct. It is obvious that the narrow lumen and the thickened wall of the transduodenal segment of the common duct normally act as a barrier to the passage of a calculus from the common duct into the duodenum.

In certain cases a distorted, feathery contour of the papilla and distal duct segment is accompanied by delayed entry of diodrast into the duodenum. These changes in the "pars intestinalis" are frequently transient. In many cases, they are secondary to alteration in physiologic mechanisms, necessarily occurring after a cholecystectomy, in others, a manifestation of papillary muscular spasm. In some, they are an indication of associated regional edema. This group includes patients with pre-existing choledocholithiasis. Trauma attending exploration of the common bile duct with the Bakes' dilators may be a factor in producing these findings. Because of the thin tortuous character of the termination of the normal common bile duct it is likely that papillary tissues would be injured by a forcible dilatation. In 1 case, a stricture of the termination of the duct appeared 6 months after original common duct exploration. This, as well as more transient cases, could have been secondary to tissue reaction

occurring in the papillary tissues as emphasized by Branch, Bailey and Zollinger, and Zawisch

It is recommended that only a small ureteral catheter 3 to 5 millimeters in maximum diameter be used as a probe. This type of instrument is thin, sturdy, and flexible. In addition, fluid can be injected through the ureteral catheter to demonstrate the actual patency of the choledochal canal.

SUMMARY

1 Fifty postoperative indirect cholangiograms on 41 patients have been reviewed. Roentgenographic and fluoroscopic descriptions correlated with clinical findings of the normal and abnormal common bile duct have been given. In this series abnormalities in the cholangiogram included (a) choledocholithiasis, (b) spasm at the termination of the duct, (c) stricture of the common bile duct, and (d) reflux into the pancreatic duct from the common bile duct.

2 The importance of careful fluoroscopic observation during cholangiography was stressed.

3 The course of the normal common bile duct has been described as a constantly curving tube which was composed of extraduodenal and transduodenal segments. The most distal portion of the extraduodenal segment was identified as "transpancreatic," when its contour was straightened and its diameter decreased.

4 The average diameter of the extraduodenal common bile duct on the cholangiogram has been found to be 6.9 millimeters. The average diameter of the orifice of the common bile duct within the duodenum was 1.5 millimeters.

5 The transduodenal segment of the common bile duct had a funnel shape and a decreasing diameter, the lumen of which terminated as a filamentous canal. There was no evidence that an "ampulla" was present. It was suggested that the termination of the common bile duct be designated only as the "papilla."

6 For routine operative demonstration of patency at the termination of the common bile duct, it was recommended that a soft, thin, flexible and hollow instrument, such as the ureteral catheter be used.

CHANGES IN RENAL FUNCTION FOLLOWING URETERAL TRANSPLANTATION

HANS R SAUER, M D, MICHAEL S BLICK, M D, and
KENNETH W BUCHWALD, M.A, Buffalo, New York

AS a result of the advancements made in modern surgery, ureteral transplantation has become a procedure which is more widely employed not only by the urologist but also by the general surgeon and gynecologist. For this reason it is more important than ever to be familiar with those factors which influence success or failure in this type of operation.

In the past, emphasis has been placed predominantly on the surgical aspects of the problem and a variety of technical modifications have been devised in order to reduce the occurrence of complications characteristic of this procedure. In addition, well planned preoperative and postoperative management has been recognized to have contributed materially to the improvement of the postoperative results.

While it cannot be denied that the above mentioned factors are of major importance, it has become increasingly evident that other phenomena such as kidney function, as well as morphology and dynamics of the upper urinary tract, have an equally great influence on the outcome of each individual case. It appears from a study of the literature that the importance of these factors has not been sufficiently appreciated in the past, and it is the purpose of this report to present results of investigations which were carried out at the Roswell Park Memorial Institute in an attempt to examine the effect of ureteral transplantation on renal function. The data obtained on 20 patients who underwent various methods of ureteral transplantation are believed to be of sufficient interest to warrant their publication at this time.

In conducting these investigations the authors adopted the following procedures: Blood chemistry studies, and, wherever feasible,

phenolsulfonphthalein tests as well as quantitative determinations of the urea nitrogen output in the urine were carried out daily before and after operation. The data obtained were correlated with the findings of excretory urograms which were made subsequently at regular intervals. Accurate calculation of phenolsulfonphthalein excretion and urine urea elimination encountered no difficulties in patients with cutaneous ureterostomy where the collection of uncontaminated specimens was possible for an indefinite period of time. However, following ureterointestinal anastomoses admixture of blood did not permit, in some cases, accurate phenolsulfonphthalein determination during the first 24 to 48 hours following operation, and, as a rule, measurement of the urine urea output had to be discontinued after the 5th to 7th postoperative day because contamination of the specimen with large amounts of feces made further tests impractical.¹

In the consideration of the effect of ureteral transplantation on kidney function a distinction was made between patients with no demonstrable gross disturbance of the upper urinary tract physiology and patients where evidence of obstruction suggested pre-existing kidney damage. This was done for the following reason: Postoperative impairment of renal function was the rule in the 1st group of cases, whereas improvement took place in some cases of the 2nd group. The results obtained in both categories indicate in general that the extent of changes of kidney function depended primarily on the type of transplant that was employed.

¹For the purpose of separating urea nitrogen from the nitrogenous waste products of the stool the following procedure was adopted: The 24 hour specimen was filtered and an aliquot portion of it was used at first to determine the total amount of ammonia nitrogen after digestion with urease. Thereafter the ammonia nitrogen of the specimen was calculated. The difference between the ammonia nitrogen after digestion with urease and ammonia nitrogen of the specimen represents the urea nitrogen.

first stage Coffey I procedure obviously because nitrogen balance was maintained during the critical days by nonimplanted side

Ureterosigmoidostomy (Coffey II) During the further course of these investigations the question presented itself as to whether or not such a severe degree of kidney function impairment might be avoided by the employment of the Coffey II operation, where catheters assure free drainage of urine from the implanted side during the first postoperative days. To this end analogous studies were carried out in a group of patients in whom modified 1 stage bilateral or 2 stage Coffey II operations were performed. In carrying out these procedures a No. 8 or 10 F whistle tip catheter was inserted for a distance of 10 centimeters into the ureteral stump before the distal end was buried into the sigmoid colon. In all cases the catheter was expelled spontaneously between the 5th and 7th postoperative day after admixture of stool had necessitated removal of the rectal drainage tube.

The results of these investigations indicate that suppression of kidney function was much less severe following a Coffey II procedure than in the group of cases where the Coffey I technique had been employed. It is evident from Graphs 5 and 6 that urine was eliminated

Urea n
GMS

Graph 6 Adequate elimination of urine urea nitrogen and phenolsulfonphthalein following bilateral Coffey II operation

following this type of operation not only in sufficient quantities but that it contained apparently adequate amounts of urea during the early postoperative period. In one of our patients with a poorly functioning left kidney where a first stage right Coffey II transplant had been carried out, it was even observed that the output of urea from the implanted side was sufficient enough to maintain the patient's urea nitrogen balance. Accordingly

it was determined that phenolsulfonphthalein excretion showed only moderate impairment compared to preoperative values and there was no elevation of the blood nonprotein nitrogen during the first 5 postoperative days. The transient slight elevation of the nonprotein nitrogen to 44 and 46 milligrams per cent during the following 2 days might be explained by the assumption that unimpeded drainage from kidney was interfered with temporarily after the catheter had been expelled (Graph 7).

A comparison of the aforementioned data shows that the Coffey I operation produces a much more severe impact on kidney function during the early postoperative period than does the Coffey II procedure. Nevertheless, study of renal function during the later postoperative stages disclosed that, after the initial critical period had been overcome, neither of these methods was superior with regard to the ultimate functional results. This is enhanced by the fact that excretory urograms, which were made at 1 to 2 month intervals beginning on the 12th day after ureterosigmoidostomy, showed equivalent structural changes of the upper urinary tract regardless of whether the Coffey I or II technique had been employed (Fig 1). Furthermore, in both groups kidney function tests 2 to 3 weeks following the 1st stage operation showed similar degrees of functional suppression and study of the urograms suggested an equally marked quantitative difference in the excretion of dye in favor of the nonimplanted side.

Investigations of the more remote effects of ureterosigmoidostomy on kidney function by means of measuring the output of phenolsulfonphthalein and urine urea nitrogen were handicapped by the obvious difficulty in obtaining uncontaminated samples of urine for examination. However, in patients with unilateral intestinal implants who had been subjected to the routine preoperative preparation for the 2nd stage operation, it was usually possible to collect suitable samples for functional tests through a rectal tube which was inserted for 24 hours preceding surgery. In general, the interval between both stages varied from 17 to 21 days, but in 2 patients who developed postoperative complications after the first operation transplantation of the

Graph 7 Nitrogen balance maintained by implanted side while other kidney ceases to function. Partial recovery of nonfunctioning kidney occurred following 2nd stage procedure (Fig 2).

opposite side was postponed for 3 and 4 months respectively. The results of these tests revealed interesting data. It was found that a marked degree of functional impairment on the implanted side continued to persist and that the extent of this impairment was usually much more severe than could be anticipated from the urographic findings. This statement is illustrated by graphs 8 and 9 from which it can be seen that the amount of urea and phenolsulfonphthalein excreted from the implanted side remained markedly reduced not only one but equally so 4 months following the 1st stage operation.

Graph 8 Demonstrates marked impairment of renal function of the implanted side 3½ months following first stage Coffey I operation

despite the fact that diodrast was eliminated satisfactorily

In view of these findings the question presented itself as to how much reliance could be placed under these circumstances on the ability of a kidney to maintain nitrogen balance during a period of severe functional derangement of its mate which must be expected to occur if a 2nd stage Coffey I operation is planned. The results obtained during the course of these investigations indicate that the reserve power of the kidney on the implanted side is apparently greater than the functional tests performed before the 2nd operation would lead one to believe. No significant ele-

vation of the blood nonprotein nitrogen developed even in patients where a 2nd stage Coffey I procedure had been employed and the elimination of urine urea nitrogen as well as phenolsulfonphthalein excretion exceeded expectations. For instance, it is evident from graph 8 that during the 24 hour period preceding the 2nd stage Coffey I ureterosigmoidostomy the output of urine was practically equal from the rectum (830 cc) and from the bladder (800 cc). Nevertheless, the rectal sample contained only 0.6 grams of urea nitrogen compared to 1.9 grams eliminated in the bladder specimen. Following surgery the total amount of urine urea nitrogen remained satis-

Fig 2 Partial recovery of nonfunctioning left kidney following Coffey II ureterosigmoidostomy

factory and more or less in proportion to the quantity of urine produced. A transient elevation of the blood nonprotein nitrogen to 49 milligrams per cent which developed on the 2nd postoperative day did not cause clinical symptoms. Graph 9, where a 2nd stage Coffey II procedure was employed, demonstrates even more convincingly that marked functional impairment of the previously implanted side should not deter the surgeon from carrying out a 2nd stage operation in patients who are otherwise considered suitable for surgery.

EFFECT OF URETERAL TRANSPLANTATION ON RENAL FUNCTION IN PATIENTS WITH PRE-OPERATIVE RENAL DAMAGE DUE TO URETERAL OBSTRUCTION

It is obvious that the problem presented in this group of patients is entirely different. In the past cutaneous ureterostomy was considered to be the only suitable method to deviate the urinary stream in patients with renal damage due to markedly dilated ureters inasmuch as this procedure which entailed comparatively little risk was known to induce partial recovery of renal function. On the

other hand, ureterointestinal implantation was thought to be contraindicated in these cases because it was feared that such an operation would add insult to injury. However, recent workers (Ferris, Priestley, Marshall) have convincingly demonstrated that even a high degree of obstruction with markedly reduced kidney function need not necessarily be considered a deterrent for ureterosigmoidostomy. Our investigations agree. For instance, in one of our cases where the left kidney was damaged to such an extent that gradual cessation of urinary output developed between the 1st and 2nd stage operations (Graph 7), partial recovery of kidney function took place following implantation of the obstructed ureter into the sigmoid as can be seen from the excretory urogram made on the 12th day after the 2nd stage operation (Fig 2).

EFFECT OF EXTENSIVE NONUROLOGICAL SURGERY ON RENAL FUNCTION IN CONTROLS

No evidence of changes of kidney function was determined during postoperative course in 5 control patients who underwent major surgical procedures for gastrointestinal disease.

Fig 3 a, Severe degenerative changes of the collecting tubules b, Minimal degenerative changes in the renal cortex

Comment The aforementioned investigations represent an attempt to evaluate the importance of those factors which influence renal function following various methods of ureteral transplantation. These studies were prompted by the occurrence of uremia which developed in some of our patients following bilateral Coffey I ureterosigmoidostomy although the daily output of urine exceeded 1,000 cubic centimeters. Recent experiences at the Mayo Clinic conform with these observations. Priestley, by referring to investigations of Ferris, emphasized that a transient rise of the blood nonprotein nitrogen occurs commonly following this procedure and the alteration of the blood chemistry, which develops shortly after operation, is believed to be due to reabsorption of nitrogenous waste products from the large bowel. In support of this theory Priestley and Ferris infer that this complication may be overcome by the use of frequent irrigation of the rectosigmoid.

It was certain from the beginning that investigation of this subject, which heretofore had not been explored, presented a fascinating challenge. As was anticipated, these studies did not add materially to the present knowledge of changes in kidney function following cutaneous ureterostomy. However, during

the course of our investigations it became apparent that ureterosigmoidostomy created various degrees of derangement of renal function, the severity of which had not been sufficiently appreciated as a whole.

It must be surmised that many factors determine the extent of kidney function impairment following ureterointestinal transplantation, but the most important ones are (1) postoperative edema at the site of anastomosis, (2) injury to the blood supply of the ureteral stump, and (3) interference with the normal dynamics of the upper urinary tract. Of these, edema at the site of implantation plays the most decisive role inasmuch as it represents a complication which, although it may be reduced by perfection of the surgical technique, cannot be avoided completely. Once it becomes manifest it causes not only varying degrees of urinary obstruction but also compression of those blood vessels which maintain the blood supply of the ureteral stump within the trough. While it is realized that adequate vascularization of the implanted ureter is of vital importance for the successful outcome of ureterosigmoidostomy, it is not believed that this factor has a significant influence on renal function during the early postoperative period with which these investigations were pri-

marily concerned. Injury to the blood supply of the ureter is more apt to have an adverse effect on kidney function during the later stages when insufficient circulation may be one of the contributory phenomena to stricture formation at the site of anastomosis.

Evidence collected during the course of our investigations rather suggests that postoperative edema with resulting back pressure is primarily responsible if severe functional derangement of renal physiology develops during the initial postoperative period following an otherwise successful ureterosigmoidostomy. This statement is supported by the observation that serious kidney function impairment could usually be avoided by employing a modified Coffey II technique where catheter drainage offset the obstructing effect of edema during the first postoperative days. On the other hand, the inadequate elimination of urine urea nitrogen, which in general was observed to occur during the early stages after a Coffey I operation, indicates clearly that this procedure deprives the kidney, at least temporarily, of its ability to maintain nitrogen balance. Yet, even following a bilateral Coffey I procedure, clinical manifestations of renal insufficiency need not develop necessarily as long as adequate restoration of kidney function takes place before the blood non-protein nitrogen shows marked elevation. As a rule, partial recovery of renal function occurs after the 4th to 6th postoperative day, but, should functional imbalance persist beyond this period uremia is bound to develop and uremic death may ensue even though the patient continues to eliminate urine in satisfactory amounts. This was experienced in 3 patients who underwent a bilateral Coffey I ureterosigmoidostomy. These 3 patients were not included in this case series because they were operated upon before these investigations were undertaken. Postmortem examination in each of these 3 cases disclosed not only patent anastomoses but also absence of marked dilatation of ureters and kidney pelvis. On cut section the kidneys showed signs of pyelonephritis. Nevertheless, the macroscopic changes were not severe enough to account for uremic death. Histological study, however, disclosed characteristic findings

which seem to be peculiar to this type of renal failure. The collecting tubules which were moderately dilated showed evidence of degeneration varying in degree from cloudy swelling to complete necrosis. In some areas partially necrotic tubules were filled with casts of debris. Widespread hemorrhage and round cell infiltration into the intertubular spaces were common throughout. In striking contrast to the severity of the changes encountered in the medullary portion of the kidney was the minimal amount of involvement of the renal cortex where the glomeruli were either intact or fibrosed due to pre-existing arteriosclerotic disease. Degenerative changes of the proximal convoluted tubulus were either absent or not severe (Fig 3a and b). Altogether, the histological picture presented was quite similar to that which has been observed by Hinman during his experimental work on hydronephrosis where he states that "the tubular unit undergoes progressive dilatation, collapse and atrophy, with the glomerulus resisting longest."

In the light of Hinman's investigations on hydronephrosis these pathological changes must be considered important inasmuch as they suggest a plausible explanation for the mechanism of transient renal failure which is apt to develop following a Coffey I ureterosigmoidostomy. Compression of the ureteral lumen by postoperative edema at the site of implantation is bound to injure the functional efficiency of the kidney which is forced to secrete against rapidly developing back pressure. While increased peristaltic action of kidney pelvis and ureter may be strong enough to overcome partial ureteral obstruction at the site of anastomosis it is evident that the sudden rise of the intrapelvic pressure has a depressing effect on the function of the lower renal segments. In consideration of these factors, which are undoubtedly in part responsible for the aforementioned characteristic pathological changes, the inadequate elimination of waste products in the urine of these patients is not surprising. As long as these conditions exist it may be presumed that function of lower nephron remains depressed to such an extent that the urine eliminated represents nothing but a glomerular filtrate.

If these changes persist permanent kidney insufficiency is bound to occur and uremic death will ensue if both kidneys are involved. In most instances, however, partial recovery takes place before renal damage becomes irreversible. In this case restoration of functional balance may be due either to subsidence of the obstructive edema or readjustment of the kidney to the altered hydrodynamics.

The degree of recovery of renal function depends on several factors such as adequacy of the anastomosis, original functional efficiency of the kidney and the patient's general condition following surgery. In addition, the type and severity of secondary infection plays an important role. In patients with unilateral transplants where the recovering kidney has to compete with a normally functioning mate the principle of renal counterbalance comes into play. This principle must be taken into consideration in the evaluation of the functional reserve power of a kidney which has withstood the impact of ureterosigmoidostomy. Hinman in his discussion of the treatment of unilateral hydronephrosis emphasizes, that "stimulation to repair, even after the most highly successful treatment of the cause of the obstruction, is not so active or great as when this is the only kidney, or a similar condition or disease is present in the opposite side." This statement is in agreement with our observations which indicate that functional recovery of the injured kidney remained limited as long as function of the opposite kidney was unimpaired. However, it appeared from the results of functional tests that improvement continued as soon as the renal counterbalance was altered following the 2nd stage operation.

Our own experiences with intestinal implantation of dilated ureters are too limited as yet to permit final conclusions. However, it may be presumed that the impact of this operation on renal function will be less sudden and severe than in normal cases inasmuch as the kidney has already been exposed to pre-existing back pressure. Thus, it can be anticipated that additional alteration of the hydrodynamics will cause a much milder shock to the kidney which need not lead to renal insufficiency. Another factor reducing the adverse effects of ureterosigmoidostomy in patients with dilated

but not fibrosed ureters is the fact that edema at the site of anastomosis will not obliterate the ureteral lumen nearly as readily as in a normal case. Even if extreme narrowing occurs it can be overcome more easily by the hypertrophied musculature of the ureter.

To what extent, if any, reabsorption of nitrogenous waste products from the large bowel contributes to the postoperative elevation of the blood nonprotein nitrogen remains problematical. In an attempt to evaluate the reabsorption theory the following factors should be considered: (1) the urine eliminated into the rectosigmoid is drained uninterruptedly through an indwelling rectal tube. Thus, its contact with the intestinal mucosa is not only of short duration but the continuous stage of collapse of rectum and sigmoid reduces the mucosal surface, from which reabsorption may take place, to a minimum. (2) If reabsorption played a major role in the development of postoperative uremia it is difficult to understand why the blood nonprotein nitrogen maintains normal values during the later stages when, following removal of the rectal tube, not only the rectosigmoid but also large segments of the colon are in continuous contact with urine. (3) The observation that it is possible to avoid elevation of blood nonprotein nitrogen by employing the Coffey II technique or by performing 2 stage operations rather suggests that a rise of the nonprotein nitrogen level occurs primarily as a result of kidney failure and not as a result of reabsorption of nitrogenous waste products from the large bowel.

Despite the fact that these studies have been confined as yet to only a limited number of cases it is apparent from an analysis of the results that the severity of the physiopathological changes produced in the kidneys varies with the type of ureteral transplant employed. Our investigations of the effect of uretero sigmoidostomy on renal function suggest the following pattern of risk. The surgical risk of a bilateral Coffey I operation is greatest because both kidneys are likely to suffer simultaneous functional imbalance during the initial postoperative period. This danger can be materially reduced by the use of a Coffey II procedure where catheter drainage offsets the

obstructing effect of edema at the site of the anastomosis as long as the catheters remain in place. However, 2 stage operations offer the greatest margin of safety because nitrogen balance will be maintained by the nonoperated kidney during the period of functional depression of the implanted side.

In consideration of these factors it is suggested that a bilateral Coffey I ureterosigmoidostomy should not be employed in patients with marked renal arteriosclerosis, advanced pyelonephritis, or any other disease which may have diminished the kidney reserve. While a Coffey II transplantation represents a safer procedure in these cases, it is felt that a two stage operation should be preferred in order to reduce the risk of postoperative uremia. In cases where the result of a first stage implantation is unsatisfactory it is advocated for the same reason to select the Coffey II technique for the second stage operation.

For the proper evaluation of renal functional efficiency following ureterosigmoidostomy it is of the utmost importance to realize that the volume of urine eliminated cannot be used as the sole criterion as to whether or not the kidneys are maintaining nitrogen balance. For this reason it is imperative, at least during the initial postoperative period, to carry out daily blood chemistry studies in order to recognize renal insufficiency at the earliest possible moment. Thus antiuremic therapy can be instituted before clinical symptoms of uremia develop, and before the patient becomes unsuitable for an emergency nephrostomy.

SUMMARY

A report of investigations dealing with the effect of ureteral transplantation on kidney function is presented. The results of these studies indicate that the extent of changes of renal functional efficiency depends primarily on the type of transplant employed.

1 No significant immediate kidney function impairment takes place following cutaneous ureterostomy.

2 Coffey I types of ureterointestinal implantation produce such a severe impact on renal function that the urine eliminated dur-

ing the first 3 to 4 postoperative days may contain no or only inadequate amounts of nitrogenous waste products.

It follows that the urinary output alone cannot be considered a reliable criterion as to whether or not a patient is maintaining his nitrogen balance, and, in patients where functional deficiency persists over a prolonged period following a bilateral Coffey I operation, fatal uremia may ensue in spite of continued and apparently sufficient elimination of urine.

Partial recovery of kidney function takes place in these cases usually between the 4th and 6th postoperative days.

3 Coffey II types of ureterosigmoidostomy cause little or no suppression of renal functional efficiency during the early postoperative period.

The possible causes for the severe degree of functional derangement of kidney physiology which occurs following a Coffey I procedure are discussed, and it is surmised that edema at the site of the anastomosis is primarily responsible for the changes observed.

Accordingly, the following pattern of risk for ureterointestinal transplantation is suggested. The surgical risk of a bilateral Coffey I operation is greatest because both kidneys are likely to suffer simultaneous functional imbalance during the initial postoperative period. This danger can be materially reduced by use of a Coffey II procedure. However, 2 stage operations offer the greatest margin of safety because nitrogen balance will be maintained by the kidney not operated upon during the period of functional depression of the implanted side.

THE BEHAVIOR OF BONE GRAFTS

THOMAS HORWITZ, M D , F A C S , Indianapolis, Indiana

THE reports on bone grafting which have emanated from military hospitals during and following the recent war, have shown a rather constant adherence of their authors to the use of well established procedures (6, 9, 13, 14, 22, 29, 33, 36) These authors have reported a 55 per cent to 126 per cent incidence of failure following the first bone graft operation in their cases In the main, they have used cortical bone, supplemented in some instances by cancellous chips or strips of bone

The use of cancellous bone to reconstruct osseous defects and to supplement cortical bone grafts in the treatment of ununited fractures and in arthrodesing operations (2, 16, 17, 30), has evolved from the work of Matti, who, in studying the fate of bone grafts, used spongia from the greater trochanter and iliac crest because he believed that this type of bone became vascularized more readily than cortical bone (4, 30, 32, 34, 35, 43) Luckey and Adams utilized iliac bone in some of their later cases of ununited fracture of the long bones (27.4 per cent of 164 cases) in the form of strips placed along the fracture site Gilson and Loadman, reporting their use of cortical and cancellous grafts in 105 initial bone graft operations with a 20 per cent incidence of failure, observed that in 23 cases in which iliac bone was used, either as slivers or as blocks with one cortical surface, the grafts united successfully in 88 per cent It was their opinion that while cancellous bone became united more rapidly than cortical bone grafts, they required protection against injury for a longer time Lambert and the writer (24) utilized iliac bone extensively in their military cases and they developed the use of massive iliac grafts which included one or more cortical surfaces, reinforcing the stability of these grafts by metallic plate fixation In their second report, they (23) had begun to realize the deficiencies of this type of bone as graft material in certain

localities and, also, they were limiting the use of the metallic plate to selected cases

The recently published work of Abbott and his coworkers (2), defining certain new principles relative to the use of cancellous and cortical bone as graft material, appeared a little too late to be applied and evaluated on the wide scale possible in military war surgery However, as the result of this report and by reason of his additional experiences, the writer's concepts regarding the use of cortical and cancellous bone as graft material have become more crystallized Specifically, this experience has been derived from the following 85 patients on whom 91 bone graft operations were performed in a military hospital, iliac bone having been used in 85 instances, cortical bone in 5 and both types of bone in one, 10 civilian patients with ununited long bone fractures in whom iliac bone grafts alone were utilized, and 25 civilian patients in whom cortical bone grafts had been employed in the treatment of the same lesion Histologic studies were made on specimens, removed at the time of reoperation, of iliac bone grafts in 6 patients and cortical bone grafts in 2 patients

THE NORMAL BEHAVIOR OF TRANSPLANTED CORTICAL AND CANCELLOUS BONE

In discussing massive bone grafts, reference is made to the dominant osseous component, for no large graft is entirely cancellous or cortical in its structure (Fig 1)

It is generally agreed that most of the mature cells in a bone graft fail to survive the transplantation and that the only cellular elements which do survive are those which form the so called endosteal layer and a few elements in the cambium layer of the periosteum The cells in these layers appear to have osteogenic properties In a cortical graft the fully mature cells die and the only channels for the invasion of new vessels and newly formed bone are the Haversian canals and the surfaces in immediate contact with the host bed (38, 39) In the instance of a large cortical bone trans

Work completed while Frederick Brown Fellow in Orthopedic Surgery Hospital for Joint Diseases New York New York

Fig 1 a, Left two specimens, are sections through the wing of the ilium, showing its cancellous structure and the outer and inner cortical surfaces which give strength to this type of graft. This factor is well demonstrated in the roentgenograms of similar sections in c. The deficiencies of this type of graft are the limitation in its length due to the normal curvature of the iliac wing and its variable thickness. a, Right two specimens, are cortical grafts removed from the tibia and fibula respectively. Note that there is some spongiosa on the deep surface of the tibial graft, and this is illustrated well in the roentgenogram of a tibial segment in b.

Fig 2 a, Ununited fracture of the ulna following a compound fracture incurred in battle, which had been treated by tibial grafting. Good union appeared to have been secured. There had been no postoperative complications or injury and the forearm had been splinted for 1 year. The center of the tibial graft has resorbed with recurrence of nonunion, 18 months following the initial bone graft operation. b, Nonunion of the femur with a gap-defect of several inches following a compound, comminuted fracture incurred in battle. The defect was bridged with a massive iliac graft fixed with screws, and by multiple sliver grafts, also from the ilium and placed in a previously prepared acrylic "trough." The lower extremity was supported in skeletal traction suspension. There was no postoperative infection or injury. Six months later the grafts were observed to resorb and disappear, with recurrence of nonunion.

Fig 2

plant, new bone is deposited at first largely on its surfaces, and, indeed, a densely sclerotic graft may become incorporated within the host bone without becoming fully replaced by new bone.

Entirely different conditions prevail in the instance of cancellous bone by virtue of its sponge-like architecture (Fig 1). Here the open spaces contain cellular bone marrow and blood vessels and communicate freely, either directly or through fine apertures in the lamellae and trabeculae. What is more, each

trabecula has its own endosteal layer. The situation in cancellous bone, therefore, is more receptive for survival of cellular elements and for early invasion and replacement by new bone, and while this pertains particularly to grafts which are small and thin, it is also manifest in the more massive type of graft. Although a portion of a massive cancellous graft will fail to survive, the peripheral portions remain viable while the more central portion becomes rapidly revitalized. On the other hand, such a massive graft from the ilium, by virtue

Although the graft may be considered as united at its proximal and distal contacts with the shaft fragments, there is a distinct interval where it crosses the fracture site. b and c, Iliac grafts for ununited fractures of the radius following compound fractures incurred in battle 6 months postoperatively. The distal end of the ulna was resected in both instances to permit repositioning of the radial fragments and correction of the associated radial deviation of the hand and wrist. Although the bone grafts in a, b, and c appear to be united to the host fragments, they still retain the architectural features of the donor bone. Until they assume features of the host bone, possibility of refracture must be guarded against.

Fig 4 a, Ununited fracture in the middle third of the femur complicating a simple fracture and treated 9 months previously by a massive iliac graft, iliac silver grafts and metallic plate fixation. The bony union is secure and the iliac grafts have begun to assume the architectural features of the host bone. b, c, A cortex in the medullary cavity are now appearing. b, Compound fracture of the femur in-

curred in battle, with a gap-defect and a narrow bridge of bony union posteriorly. A reinforcing iliac graft was applied anteriorly and the defect filled with iliac shivers 3 months previously. Although the graft is beginning to unite to the shaft, it retains its original features. c, Non-union of the femur complicating a compound battle fracture, which had been treated by a massive iliac bone graft and metallic plate fixation 5 months previously. It is now felt that cortical bone is preferable as graft material in the shaft of long bones where cortical bone normally predominates. d, Ununited fracture of the tibia following a compound battle fracture treated by medial shifting of the upper fibular shaft following its osteotomy and transfixion by screws to the proximal tibial fragment, and the application of a massive iliac graft to the posterior surface of the fracture site without any screw fixation. The graft was not applied anteriorly because of soft tissue scarring in this area. Union of the tibial fragments is apparent 5 months postoperatively. The cancellous graft seen in its distal portion between the tibia and fibula is not too well incorporated, nor have the architectural features of the tibial shaft been reformed as yet.

of its one or more cortical surfaces gives a good measure of stability and internal fixation.

Plastic surgeons (11, 19, 37) have observed that skull and facial defects filled with cancellous

lous chips which are admirably suited for molding, feel firm as early as 10 days postoperatively. With the use of cancellous bone grafts, fixation of a small joint, such as the wrist, may become manifest, clinically, as early as 4 weeks following arthrodesis (without metallic fixation), while fusion of the spine or larger peripheral joints appears, radiographically, to be consolidating well by the twelfth postoperative week.

Until a bone graft, whether it is cortical or cancellous, becomes fully reconstituted by new bone of adequate strength, it may fracture or collapse, a complication which is observed even when the grafted part has been well protected (Fig 2). This is a particular hazard where the graft is massive and has been used across the sclerotized fragment ends of an ununited fracture or to bridge a gap defect, and thus contacts little or no viable osseous tissue in its central portion (Fig 2b). This "weak period" may occur later than the terminal second or the third month usually referred to (8, 15, 21). The writer has observed a case in which a massive cortical graft, employed to bridge a gap defect of the ulna in the presence of an intact radius, had fractured 18 months postoperatively, although there had been no injury or postoperative infection, and part had been protected by a splint for 1 year (Fig 2a).

When cortical fragments unite across a defect which has been filled with cancellous bone, the transplanted bone appears homogeneous and retains its original features for a long time (Figs 3 and 4). Until such an area differentiates into cortex and medulla, it is structurally weak and may give way. How long does this differentiation of cancellous bone take? The writer has observed the "ground glass" roentgenographic appearance of a cancellous graft retained for as long as 1 year. Abbott and his coworkers (3) studied the histologic specimens removed from 8 iliac grafts as late as 3 years following transplantation, and they observed complete differentiation in a tibia 1½ years postoperatively, and in an opponens thumb-strut 2 years following surgery. On the other hand, differentiation of a cortical bone graft in a bed of cancellous bone (for example, at the ends of long bones and in the spine) is also prolonged and, by roentgenographic stand-

ards, this may never fully occur. Such cortical struts, when massive and dense, may not become replaced by, but rather become incorporated within, new bone formation.

These findings form the basis for conclusions such as Abbott and his coworkers have arrived at. If an ununited fracture or incomplete osseous defect occurs at the end of the shaft of a long bone where spongy bone normally predominates, the type of graft employed should be predominantly cancellous. With adequate fixation and approximation of the fragments, these grafts will become rapidly and intimately incorporated within, and assume the features of, the host bone. At or near the center of a long bone where cortical bone predominates and where strength is required throughout a longer period of revascularization and revitalization, cortical grafts are preferred.

Cancellous chip grafts or sliver grafts, which become rapidly incorporated when employed where spongy bone normally predominates, are not advisable alone in the repair of long bone defects at or near the center of the shaft. However, in this area, a massive iliac graft with its one or two cortical surfaces will serve admirably when sufficient cortical bone is not available, or in order to spare one lower extremity when the opposite one is the site of operation. Such a graft is almost as rigid as a cortical graft of like dimensions, and it has the advantage of rapid incorporation by virtue of its predominant cancellous component. It has the disadvantage of limited length because of the normal curvature of the wing of the ilium, and of variable thickness (Fig 1, a and c). The writer no longer favors the use of iliac grafts alone in the repair of a complete gap defect in the shaft of a long bone, but agrees that the dual cortical graft, supplemented with cancellous strips, is a more effective mechanical procedure (5) and is fraught with less likelihood of failure (6). Where possible, the defect in these cases would be diminished by shortening the extremity. The dual type cortical graft operation (7) tends to reconstruct the cortical walls and medullary cavity of the shaft. Cancellous grafts placed along the sides of or encircling the cortical grafts, line the latter with a type of bone which is more readily revitalized and which serves to reenforce the

major grafts, in turn hastening their revitalization and replacement by new bone. When the condition of the soft tissues will not permit the introduction of so much bone in one stage, the reinforcing cancellous strips could be inserted at a second stage preferably preceding or during the resorptive phase of incorporation of the major graft.

There are sound arguments for and against the use of plate fixation at the time of the bone graft operation. Luckey and Adams believe that a metal plate encourages resorption of the graft by removing the effects of functional stress and strain which are necessary for the development and growth of the graft once it has become united in its bed. It is this local factor which has encouraged the use in some foreign clinics of the intramedullary nail as a method of internal fixation in the treatment of pseudarthrosis (44). Gilson and Loadman, on the other hand, suggest that the metal plate may prevent failure by taking away some of the strain from the bone graft. The writer now believes that metallic plate fixation is indicated specifically in the repair of osseous defects in certain anatomical areas, such as in the upper half of the femur and humerus where the lever action of the extremity may prove vicious (Fig. 4a, b, and c). The effectiveness of the internal fixation secured initially by metallic screw fixation of a large bone graft, becomes endangered during the resorptive phase of incorporation of that graft. Adequate support may be afforded in these cases by external fixation when the fracture site is within or distal to the lower part of the femur or humerus, especially in the presence of an intact bone adjacent the fracture site (for example, the fibula or a forearm bone), and particularly where there has been minimal soft tissue dissection during surgery (Fig. 3a, b, and c). Indeed, in these latter cases no internal fixation whatever may be required (20) (Fig. 4d). Where, however, reduction is difficult to maintain the soft tissues will not hold the graft and internal fixation of the graft is necessary.

COMPARISON OF RED AND YELLOW MARROW CANCELLOUS BONE AS DONOR AND HOST

Clinically cancellous bone containing red marrow, such as bone from a rib, the ilium or

the greater trochanter, appears to be better graft material than spongy bone containing yellow marrow, as found in the ends of a long bone such as the tibia (30). This is fortunate since both iliac wings offer an enormous amount of bone for transplantation the removal of which need result in no disability (23, 24). Abbott and his coworkers (3) may be correct in attributing this difference between the osteogenic properties of both types of cancellous bone to the inhibitory effect of fat on the formation of new vascular tufts and new bone.

The experiments of Huggins and associates (25, 26, 27) are enlightening as to the distribution of red and yellow marrow. These authors demonstrated in rats that the occurrence of increased hemopoiesis, vascularity, and protein framework of marrow, was directly related to elevation in body temperature. Yellow marrow was found in those bony components furthest removed from the trunk—for example, in the tail and the extremities. Also transplantation of these peripheral segments into the body wall or peritoneal cavity caused the transformation of marrow from yellow to red. In their experimental animals, actual intramedullary temperature measurements increased from the periphery of the extremities to the trunk. These findings are consistent with those in the human skeleton, where the cancellous bone of the osseous components of the trunk (for example, the sternum, ribs, vertebrae, pelvic bones, and the bony components of the shoulder and hip joints) contain red marrow, and the cancellous bone in the extremities (for example, the tarsal and carpal bones, and at the ends of long bones) contain yellow marrow predominantly.

What pertains to bone as grafting material also applies to bone as host material. Spongy bone is a more receptive host tissue than cortical bone, both types of host bone are more receptive to cancellous than to cortical bone grafts, and, finally, a cancellous bed containing red marrow may be even more receptive than a bed of yellow marrow spongy bone.

THE BEHAVIOR OF BONE GRAFTS IN THE PRESENCE OF INFECTION

As recently as 1934, Dickson cautioned against the use of a bone graft in the presence of

of infection, even if low grade. Experience in the late war has shown that a bone graft may survive a complicating postoperative infection. For example, Luckey and Adams observed latent infection in 22 of 228 cases, yet union occurred in 17 of this infected group. In the writer's series of 91 bone graft operations (23), successful union occurred in 6 of 11 infected cases. Indeed, the use of chemotherapeutic and antibiotic agents has encouraged some surgeons to recommend the filling of draining, obviously infected, bone defects with cancellous bone chips, simultaneously with any necessary soft tissue repair (1, 10, 18, 40). Others are agreed, however, that it is less hazardous to use such grafts a suitable time following saucerization and temporary split skin coverage (28, 31, 41, 42).

In the reconstructive bone surgery of previously compound fractures, especially those which have been frankly infected, there is a hazard of recurring infection, during which the survival of transplanted tissue, particularly bone, becomes jeopardized. Cancellous bone appears more capable of withstanding infection than cortical bone, perhaps because of its greater permeability and more rapid revitalization (1, 18, 23). If infection occurs and is mild and if surgical intervention can be withheld or minimized, portion or all of graft may survive, and operation may still succeed.

The incidence of recurrent infection in these cases appears to be related to the "waiting period" between the time of wound healing following the original compounding and the time of reconstructive surgery. A period of 3 months or even less has been accepted by many as a safe interval prior to definitive surgery. Farrow, analyzing the incidence of 11.5 per cent infections in 156 bone graft operations for 137 cases with ununited fractures and 19 cases with limited union, 80 per cent of which had been compound, observed that the incidence of infection diminished rapidly as the "waiting period" was prolonged. This incidence was 40 per cent in 15 cases with a waiting period of 1 to 3 months, 20.5 per cent in 39 cases with a waiting period of 3 to 6 months, and no infection in 18 cases with a waiting period of 6 to 8 months. Lambert and the writer (23), adhering to a 6 month waiting in-

terval, reported an incidence of recurrent infection in 12.1 per cent of their 91 bone graft operations. In view of these and other reports, a "waiting period" of 8 months or even longer appears advisable at the present time if the danger of relighting a latent infection is to be reduced to a minimum.

Further light has been shed regarding these recurrent infections by Lambert and the writer (23), who obtained positive wound cultures at the time of reconstructive surgery in 9 of 18 cases with ununited fractures of long bones, 6 months or longer after all wound healing. In all of these cases, chemotherapeutic and antibiotic agents had been utilized liberally at the time of injury, during wound healing, and in preparation for the reconstructive operation. Indeed, in 1 case healing had been present for 9 months and in another for 1 year. Eight of these 9 cases had been compound fractures and 1 case was a simple fracture which had been reoperated upon. In view of the inability, at this time, to determine accurately the presence of living bacteria prior to or during surgery, and to protect fully against this potential hazard, these authors have concluded that there will continue to be an irreducible minimum incidence of postoperative infection following reconstructive surgery of compound fractures. If a bone graft operation is to be performed and there is danger of relighting a latent infection, cancellous bone is preferred to cortical bone, since this type of bone appears more capable of surviving this complication.

CONCLUSIONS

1. Cancellous bone should be used as graft material to bridge or fill an osseous defect at the end of a long bone, where spongy bone normally predominates. At or near the center of a long bone, where cortical bone predominates and where strength is required throughout a longer period of revascularization and replacement by new bone, cortical bone grafts are preferred. There will be greater assurance of union in these latter cases if cancellous grafts are used to supplement the major cortical graft. Although the fracture fragments at or near the midshaft of a long bone, will unite when bridged with cancellous bone, it will take as long as 2 years for this transplanted bone

to assume the architectural features of the host bone, and during this entire period of transformation there is danger of its collapse or refracture. Cortical bone, on the other hand, when transplanted to a cancellous bed may never fully lose its original structural features.

2 Transplanted cancellous or cortical bone undergoes a phase of resorption during graft incorporation, and while this "weak period" has been noted usually at the end of the second and during the third months, it has been observed to occur as late as 18 months postoperatively. It is during this phase that refracture of the bone graft may occur.

3 The technique of the bone graft operation, i.e., whether dual-type, onlay, inlay, intramedullary, etc., and whether or not internal fixation is to be employed, will depend entirely on the circumstances analyzed in each case. In the presence of large osseous defects with nonunion, the dual-type of graft appears to be most effective mechanically and is fraught with less likelihood of failure.

4 Cancellous bone containing red marrow appears to have greater osteogenic properties than cancellous bone in which yellow marrow predominates. The iliac wings are the source for an enormous quantity of red marrow spongy bone, and a massive graft from this region has rigidity and strength.

5 If bone is to be transplanted and there is danger of relighting a latent infection, cancellous bone is preferred to cortical bone, because of its greater ability to survive this complication. Despite the use of chemotherapy and antibiotic agents, recurrent infection has been observed as late as 1 year following wound healing in a compound fracture.

THE MEDICAL TREATMENT OF ENDOMETRIOSIS AND THE SIGNIFICANCE OF ENDOMETRIOSIS

JOE VINCENT MEIGS, M D , F A C S , Boston, Massachusetts

THE medical treatment of endometriosis has not as yet been proved to be of great importance. There can be no doubt that progression of the disease can be held in abeyance and its activity checked by medical treatment but the cure of such a lesion seems out of the realm of possibility. Miller of Hartford and Hirst of Philadelphia have presented experiences of considerable value in the use of testosterone. This hormone stopped the advance of the disease probably by inhibiting the activity of the pituitary gland as far as follicle stimulating hormone and luteinizing hormone are concerned, so that ovulation and luteinization and therefore an active, normal, ovarian-uterine cycle did not occur. It is also possible that the hormone may directly counteract the effect of estrin upon the proliferating cells of the endometrium. Miller reports that his case was made more easily operable but endometriosis was still present. It is unlikely that a pathologic state in which the lesion is often in an end-phase and which in many instances has taken years to develop would vanish following the use of any hormone. This hormone to be effective would of necessity have to be given over a period of years, for our experience on observing an adenomyoma of the rectovaginal septum following castration showed that 3 years elapsed before the lesion became white and puckered. Karnaky, judging from his personal communications with me, is very active in his advocacy of stilbestrol in the treatment of endometriosis. He states that the lesions vanish, that pain ceases, and that fertility results in many instances. He uses large doses of stilbestrol and has worked out a definite program for treatment. It is fair to say that the hormonal approach should be given every opportunity and its advocates should be encouraged to persist in their attempt to find a

satisfactory treatment. However from the very nature of the lesion, that it is endometrium which is active but misplaced, any medical treatment to cure an endometrioma must cause inhibition of the hormones that activate it. Inasmuch as medical methods of treatment are in the experimental stage, it is not possible to advise their use at the present time.

Another form of medical or perhaps better called nonsurgical treatment is the use of radiation, either radium or roentgen therapy. This method of treatment is definitely curative and yet it is not recommended unless as a secondary treatment following a surgical excision that has failed, or in a lesion so extensive that surgery is considered too dangerous to carry out. Inasmuch as endometriosis is so frequent in the age group in which sexual activity is important it is unwise to use a form of treatment that causes the menopause to develop with its ensuing effect on sexual desire and satisfaction. It must not be forgotten that castration, whether surgical or following radiation, may cause serious changes in the metabolism of bone. About 20 years after the normal menopause, osteoporosis frequently occurs and it is reasonable to expect that 20 years after castration at the age of 30, that is at 50 years of age, real bone changes may occur. Unquestionably castration has an effect upon bone, skin, and hair, and for young people this method of treatment should be avoided if possible. Radiation is an easy, simple, and safe method of treatment but this type of therapy in youth is not being used so frequently as it has been, even in the group of patients who have small fibroids with bleeding or metrorrhagia haemorrhagica. Radiation therapy can be used and it will be a most satisfactory method in a number of cases but its after effects are not desirable.

For these reasons this author is not satisfied with the use of medical treatment in patients with endometriosis. It surely will have its

TABLE I.—TWO SERIES OF CASES TAKEN FROM PRIVATE AND WARD PATIENTS 8 YEARS APART

	Consecutive cases	Endometriosis microscopically		Endometriosis grossly		Endometriosis microscopically or grossly	
		No	Per cent	No	Per cent	No	Per cent
Private Cases (1st series)	400	112	28	32	8	144	36

(2nd series)	400	23	5.75	10	2.5	13	3.25

uses, and perfection of these methods of treatment will give the surgeon or gynecologist another arrow for his bow in the cure of a usually simple but sometimes very complicated lesion. We should encourage experimental trials but not advocate their use until further satisfactory reports have been published.

THE IMPORTANCE OF ENDOMETRIOSIS

The peculiar phenomenon (8) of endometriosis, which the author believes is a result of abnormal physiology and not a true disease or tumor, has certain effects upon young women that are far from desirable. Its ability to cause pain—both intermenstrual and during menstruation—is well known. The dysmenorrhea is usually of no serious consequence and its relief by the methods suggested recently by Dr. Counsellor is obvious and not dangerous. Its advance however into the bladder, the bowel, or around the ureter is of serious consequence and its growth must be checked or the lesion removed. The cure of such lesions in these days of modern surgery is not too much to expect. However, its true importance is its effect upon the problem of reproduction. From previous studies of ward patients versus private patients it seems that the successful and educated stratum of society is most affected and this should be very important to us. We, as physicians, are in that stratum—intelligent, trained, educated, and socially minded—the so-called upper middle class as contrasted with the unsuccessful, impecunious and less educated group. This must not be misconstrued as an attempt to place us in the

snobbish society group, but we are college men, university graduates, and are supposed to be intelligent and intellectual. Apparently it is our group of society, that marries late and limits the size of its families, which is most affected by endometriosis. It is our duty to reproduce ourselves, for according to many investigators only an occasional man or woman of large intellectual stature springs from the uneducated and supposedly not so intelligent class. It is from us, the really educated, that most of the superior minds develop. If this is so, and undoubtedly it is, it would appear that we should do our share of reproducing ourselves and not leave it to the other group. It has been shown that endometriosis is much more frequent in private than in ward patients (Table I) and therefore with the recognition of these facts and with our superior intelligence it would appear that the thinkers or more intelligent group should be interested in this problem. The importance of endometriosis is in its accompanying infertility among those who by their training and education attempt to plan their marriages on the basis of security from financial worries, and their child-bearing not upon biologic laws but the rules set down by the society in which they live. To these people conformity with the "Joneses" is more important than the production of the best children of the nation. Carrel in his famous book *Man the Unknown* states in confirmation of this brief discussion that "Eugenics is indispensable for the perpetuation of the strong. A great race must propagate its best elements. However, in the most highly civilized nations reproduction is decreasing and yields inferior products. Women voluntarily deteriorate through alcohol and tobacco. They subject themselves to dangerous dietary regimens in order to obtain a conventional slenderness of their figure. Besides, they refuse to bear children. Such a defection is due to their education, to the progress of feminism, to the growth of short-sighted selfishness. It also comes from economic conditions, nervous unbalance, instability of marriage, and fear of the burden imposed upon parents by the weakness or precocious corruption of children. The women belonging to the oldest stock, whose children would, in all probability, be of good quality,

and who are in a position to bring them up intelligently, are almost sterile. It is the newcomers, peasants and proletarians from primitive European countries, who beget large families. But their offspring are far from having the value of those who came from the first settlers of North America. There is no hope for an increase in the birth rate before a revolution takes place in the habits of thinking and living, and a new ideal rises above the horizon." Such a philosophy falls in with the facts of the studies carried out and reported previously. Private patients, and it is presumed that they are of more superior intelligence in most instances than ward patients, do not marry early enough and do not have sufficient numbers of children who can be brought up into healthy and strong sons and daughters. Carrel suggests that "The only way to obviate the disastrous predominance of the weak is to develop the strong."

THE SIGNIFICANCE OF ENDOMETRIOSIS

As a gynecologist interested in the problem of endometriosis and long aware that it is much too frequent, and interested and somewhat alarmed at the possible injury to us by the apparent frequency of late marriage and infrequent child-bearing, I have made repetitions of my thesis since its first presentation in 1938 in an editorial in *SURGERY, GYNECOLOGY AND OBSTETRICS* (9). A paragraph from Edwin Lawrence Godkin's *Problems of a Modern Democracy* quoted in a *Book-of-the-Month Club News* helps me to feel that repetition can be salutary. This paragraph states "No one ever talks freely about anything without contributing something, let it be ever so little, to the unseen forces which carry the race on to its final destiny. Even if he does not make a positive impression he counteracts or modifies some other impression, or sets in motion some train of ideas in some one else, which helps to change the face of the world. One of the functions of an educated man is to talk, and of course he should try to talk wisely." This paragraph bolsters me in my repetition and perhaps it is a good excuse for repeating what has been written before.

In 1798 Malthus was distressed about the increasing population in the British Isles and

his worry was based upon the theory that population increased by multiplication whereas the basic food supply increased only by addition. He apparently was in favor of marital continence, avoidance of marriage, pestilence, and war to keep the population within normal limits. It so happened that his worry was not necessary at that time for shortly after his essays were published the concentration of population in cities due to the industrial revolution was followed by a decrease in birth rate, although due to newer methods of hygiene and sanitation an increase occurred in the length of life. According to Vance, whose article "Malthus and the Principle of Population" I am using freely, contraception began to be used in France about this time with the result that the birth rate of that country dropped rapidly and kept the population stable in spite of the increasing length of life. There were just as many marriages in France but not so many children. This was the beginning of an attempt to control the birth rate and if it had been used everywhere plus the advent of hygiene and the subsequent increase in length of life the Malthusian idea might have been borne out. There is no doubt that something had to happen to save the world from overpopulation. Malthus thought that each married couple should have 6 children but modern demographers, or those interested in the study of population in relation to vital statistics and social statistics, believe that 3 children per family are sufficient. Six children per family if all lived, and in these days most would live, would quickly overpopulate the countries where hygiene, sanitation, and the like are part of modern civilization. Something needed to be done about the population, and contraception, late marriage, and infrequent child-bearing were aided by two very great wars. Ireland is an example of the working of the Malthusian theory for here the population is kept at 4,500,000 and overpopulation is avoided by late marriage, by the entrance of many sons into priesthood and of daughters into the sisterhood, and by the largest percentage of unmarried and therefore unproductive women in the world. Birth control is not used in this Catholic country but stabilization of the population has been achieved.

It is interesting to note what patients in the private practice of a gynecologist do about increasing the population. The last 200 patients were questioned as to whether or not they used contraception and the results show that over 90 per cent use contraceptive methods of one sort or another. In my private practice 200 married couples, who at this time were over 38 years of age, had produced 389 children or 1 94 per couple. Further information showed that in the Gynecologic Out Patient Clinic of the Massachusetts General Hospital 196 successive patients had 650 children or 3 3 children per married couple, a little less than twice the number produced by private patient couples. Dr Clarence Gamble (1,3) of the Population Reference Bureau discloses that married college women graduated in 1923 had but 1 66 children in 1948 and that married college men had 1 85 children. The graduates of Princeton and Harvard, 25 years out of college, fathered but 1 90 and 1 83 children respectively, while the total number of women with not more than 4 years' schooling averaged 4 33 children. This must mean, therefore, that in our intelligent and successful class of society the deliberate avoidance of large families is the rule. Thus we are enthusiastic Malthusianists and our group is gradually becoming smaller while the less educated group becomes larger. It must be admitted here that 100 unselected doctors of the staff of the Massachusetts General Hospital, with their usual intelligence and farsightedness, have been an exception to these figures for these married couples who have reached 38 years of age have had 2 7 children per couple, a very satisfactory accomplishment (Table II).

Unquestionably limitation is important to society but the mistake is the use of birth control in patients who have married late and in patients who have produced but 1 child. It is the feeling of this writer, and this has often been repeated, that our children should marry young and they should have their families when young. After this has been accomplished they can then practice prevention of impregnation. I am definitely against giving contraceptive advice to patients who are young and can afford to have children. I am against giving it to newly married women over 25 for it is my belief that these are the patients who by not using their reproductive organs and by allowing their menstrual cycles to continue uninterrupted for 12 to 14 years, develop endometriosis with its important bearing upon fertility. An ovary that is adherent or a tube that is adherent, a complication of endometriosis, certainly is a definite deterrent to conception. Again to be repetitious (7) it is my feeling that we as parents should give financial aid, if we can, to our children and encourage them to have babies. The modern young married couple gets along on very little. These children of ours are the type that are important to the world. It is not large families of the poor, the unhealthy, the weak, and the unintelligent that the world needs, but families of the healthy, strong babies of our children. With a slight amount of help we can prevent the sad occurrence of our children seeking advice and help for a sterility problem that may be insoluble.

That this philosophy can lead to the ridiculous is obvious. I have a letter from a surgeon in Worcester, Massachusetts which is so apropos that I would like to quote a paragraph. The doctor writes after reading a similar article to this one in the *Annals of Surgery* for May, 1948 "I warn you I read it with a shudder and will delete all references to parents helping their children financially so that they may marry young. My case history and a little mathematics are sufficient to precipitate a psychosis at the very thought. I am though I was one of those poor benighted souls who put in a long period of training and did not marry until I was 32, my score at the box office at present is 7 children. My wife is only

43 If, in order to prevent endometriosis, I encourage the early marriage of my children with the responsibility in the background of education in private schools, colleges, and universities, I may have to borrow some money from you. If the larger physical growth of the present generation of children is paralleled by a corresponding increase in fertility, and they can ring the bell at 8 children each, I soon would have an extension of the endometriosis program to apply to 56 children!" This is a delightful commentary from a very wise and friendly surgeon, and how correct he is! But I hope all his sons will be older and established and marry young wives, as he did, and then they will be able to care for them even as the doctor has. Not all young men want to marry out of their own age group and this is the problem that is before us. Not only do I think that we should help our children financially but that industry might be able to give more wages to the young married man so that he can have children when young and healthy.

The Malthusian theory is working out among us but war and pestilence are not our methods for we prefer the use of contraceptive methods which are satisfactory in their place, which is not with the young married couple until they have produced their offspring.

A look at Table I showing the incidence of endometriosis in the private and ward patients should convince each of us of the seriousness of the problem of endometriosis and should warn all of us that our young are too precious to be sacrificed in these difficult economic days. Malthus was correct and we must pay attention to his ideas but let us not carry them out too rigorously in our educated and supposedly intelligent group!

The importance of endometriosis is its aspects and relation to infertility, and its significance is that we as parents, recognizing the facts, can help to increase the most necessary class in society and aid the world in becoming a healthier and better place.

SURGICAL PROCEDURES INVOLVED IN THE TREATMENT OF ENDOMETRIOSIS

VIRGIL S COUNSELLER, M D , F A C S , Rochester, Minnesota

THE surgical treatment of endometriosis is both of a radical and of a conservative nature. However, before presenting to you the ideas of my colleagues and me concerning some of the surgical procedures required in the successful management of this interesting entity, let me repeat what I have so often said, "There is no pelvic operative procedure which at some time is not required for endometriosis or made more difficult by its presence. Few conditions demand more surgical skill and judgment to secure the best way out of an unfortunate situation for the patient."

It seems to us that extreme caution must be used in making a decision that a patient suspected of having endometriosis has now reached the point at which she requires surgical treatment for relief. This is a simple matter if one is dealing with large chocolate cysts of endometrial origin or if there are associated pelvic pathologic conditions which of themselves need surgical treatment. I refer especially to those younger patients who complain of dysmenorrhea and who may have some slight fixation or immobilization of one adnexa or tender and tense uterosacral ligaments. One of the chief symptoms of the younger patient is menstrual pain, uncontrollable and of an increasing character. Usually in a few years there will be superimposed on this some type of menstrual disturbance and in the young married patient, there is the question of sterility. If therefore, the pelvic findings are not remarkable and definite on pelvic examination, one should be quite hesitant in advising surgical treatment and, what is more, should be quite cautious in evaluating the results which may be obtained if the patient accepts surgical treatment. However, it is an entirely different matter when the pelvic findings are definitely

those associated with extensive endometriosis or if this is associated with other pelvic lesions such as fibromyomas, ovarian cysts, hydro salpinx, and so forth.

This word of caution is injected here to try to prevent, or at least to defer, early surgical intervention in some of these young women because we have noted that there is such a variation in the threshold for pain among them, and that clinicians so frequently will make a diagnosis of endometriosis on the basis of menstrual pain alone. Certainly, by no means is endometriosis responsible for all the pelvic pain ascribed to it. There are, however, definite physical findings which are familiar to the trained gynecologist and which denote only endometriosis. These should be entirely familiar to anyone who attempts to treat surgically such an important pathologic entity in women, which is so intimately associated with their pelvic comfort, their marital relations, and their reproductive capabilities. A discussion of the physical findings in this disease is not to be incorporated here.

As a basis for discussion of the surgical procedures a series of 852 patients in whom operation was performed from 1940 through 1945 will be used. Also, I shall refer in addition to some of the difficulties inherent in performing the common pelvic operative procedures in the presence of endometriosis.

It is particularly interesting that in this group of patients only 6.2 per cent were less than 30 years of age, while 81.7 per cent were from 30 through 49 years of age (Table I). Thus, I believe, is the correct trend and is indicative of our efforts to allow the younger patient to carry on with her disability providing it is not too incapacitating. If she marries, it is to be hoped that she will have children before it becomes necessary to intervene surgically, because there is increasing evidence that surgical intervention on the uterus in patients who have a few endometrial implants does in-

TABLE I.—AGE INCIDENCE

fluence a secondary sterility. Patients who undergo operation after 40 years of age usually have other associated pelvic lesions in addition to the endometriosis.

It does seem that the pelvic structures and peritoneum of some women are different from those of others in that they do not tolerate manual manipulation or any surgical trauma. Each of you has seen the excessive contraction which occurs in the uterus of some patients when it is handled at operation and the vascular flush which also is easily induced in the peritoneum of the cul-de-sac and broad ligaments if they are subjected to the slightest trauma. These structures actually behave in the same manner as the cornea when it is touched or irritated.

Since endometriosis seems to be definitely increasing, every precaution should be taken at least on our part to prevent its occurrence. Nonsurgical intervention in the female pelvis except for acute emergency conditions may be quite helpful, since the incidence of endometrial lesions seems to be definitely increased by previous surgical procedures. In this series of 852 patients studied, 369 (43.3 per cent) had undergone previous pelvic and abdominal surgical procedures. However, only 7.0 per cent had undergone abdominal surgical procedures on structures other than the pelvic organs. Surgical procedures involving the uterus itself or its adnexa had been performed in 27.6 per cent of the cases, and dilatation and curettage and perineal surgery had been done in 8.7 per cent (Table II). Whether this is a definite factor in the causation, of extreme

TABLE II.—PREVIOUS SURGICAL TREATMENT

surgical significance, cannot be said for certain but it can be said, I believe, without question that there is considerable variation in the degree of sensitivity of the pelvic organs among women.

Whenever surgical treatment becomes indicated for endometriosis, it is on account of menstrual pain, menstrual dysfunction, sterility, associated pathologic lesions of the pelvic organs or a combination of two or more of these factors. The extent of the surgical treatment required will depend entirely on the extent of the endometrial process.

We all know that endometriosis is functioning endometrium or endometrium-like lesions in an ectopic position. Its activity is synchronized with that of the normal endometrium, so that to secure a surgical cure the ovaries, which control the activity of the endometrium, must be removed or the endometrial lesions must be excised.

The longer that surgical intervention can be postponed, the better it will be for the patient, because it is not possible to estimate before operation how extensive the procedure is going to be. If the patient is less than 35 years of age, perhaps one can perform a conservative operation and maintain both the menstrual and reproductive functions, a result which is highly desirable. However, maybe at operation it is obvious that this cannot be done without the possibility of early return of the same symptoms and difficulties. For this reason it is mandatory that the surgeon be given permission to do a radical removal of all pelvic organs if in his judgment this appears to be advisable at the time of pelvic exploration. Most young women who thoroughly understand these facts and who understand how this pelvic situation functions will not submit to surgical treatment under these circumstances.

unless they are indeed having serious disability and desire relief above everything else.

There is a situation which seems contradictory to what I have just said, and I believe that it should be briefly stated here. Occasionally you will encounter a patient whose ovaries are quite free of endometrial lesions, but it is impossible to excise completely all the implants on the broad ligaments and peritoneum of the cul-de-sac. My colleagues and I hesitate to perform castration in this type of case, but we usually perform a subtotal hysterectomy since we have found that, if the patient does not menstruate, the remaining implants stay relatively quiescent even though the ovaries are still functioning. I cannot give a good reason for this behavior except to say that it resembles some malignant implants or metastatic growths which remain quite inactive for several months or years after removal of the parent growth. Hysterectomy in a young woman must be considered radical treatment but not as radical as though bilateral castration were done also.

We feel that it is vital to the patient's welfare to conserve ovarian tissue and prolong ovarian function as long as it is possible, because some of the effects of sudden cessation of ovarian function are about as detrimental and as difficult to manage as the original disease itself. Some of these conditions briefly are atrophy and increased sensitivity of the vaginal mucosa, loss of muscle tone, and other evidences of early senility. However, forunately in no instance in which it is neces-

sary to perform castration the effects are not as severe as is common in castration for other reasons. Many of these patients will have few if any symptoms. This phenomenon is explained in part by the fact that the gradual destruction of ovarian tissue by the endometriosis has progressed, at the time of operation to such an extent that the patient has been bordering on menopause for some time. Therefore in this condition patients who are in the age group of 35 years or older will begin to have evidence of ovarian dysfunction and menstrual disturbances.

If the foregoing statements and observations are correct and they are applied in the selection of patients for surgical treatment, it will be noted that a greater number of the patients will be treated by more radical means and that surgical treatment will be delayed until the middle or later part of the thirties. Our studies in this group of patients show that 74.1 (87.1 per cent) were treated by radical surgical measures which, generally speaking, means a complete removal of all pelvic organs except in the case of those patients who have diffuse lesions in which the ovaries are uninvolved (Table III).

Conservative operations, which were, of course, directed at relief of pain and preservation of menstrual and reproductive functions, were performed in 110 patients (12.9 per cent of the total cases). Of these, 10 (9.1 per cent) underwent presacral neurectomy in addition. This was combined with excision of the accessible implants in 2 patients, excision of one adnexa in 3 patients, and the removal of one ovary in 3 patients. Owing to careful selection of patients the results of presacral neurectomy have been excellent.

If a presacral neurectomy is to be done as one of the conservative measures, it should be limited to those situations in which the lesions are confined mainly to the uterus, uterovaginal ligaments, and vesical tissues. If the lesions are on the parietal peritoneum or intestine they are not affected by this procedure. Furthermore, it is not a procedure to be undertaken hastily, and it must be carefully executed, especially in securing the branches which pass downward along the left common iliac vein, if one is to avoid severe hemorrhage.

It must be remembered too, that this nerve can regenerate completely within 3 to 5 years and have all the sensitivity restored

Menstrual abnormality in endometriosis is rather high and is one of the symptoms which the patient is most anxious to have corrected. In this series 688 patients (81 per cent) complained of some type of abnormality. Some of these abnormalities were not due to any gross pathologic change in the ovaries but were attributed to ovarian-pituitary and thyroid imbalance or dysfunction. However, in 496 patients (58 per cent) there was menorrhagia or metrorrhagia which could be directly attributed to endometrial or other lesions of the ovaries and uterus. From this, one can assume that about 58 per cent of the patients at least will require surgical intervention for adnexal or uterine lesions which most likely are producing the menstrual disturbances.

The dysmenorrhea which these patients complain about is variable and, as previously referred to, must be carefully selected if the surgical intervention is primarily for the relief of pain. Patients may have extensive lesions without much pain, as was the case in 145 patients (17 per cent). Many of these lesions are in conjunction with large fibroids and for some reason are relatively painless. This same situation obtains in cases of large endometrial chocolate cysts, in which all ovarian tissue is about destroyed from pressure of the old blood. In these situations also there is not much pain. On the other hand, one or two small implants properly situated on the uterosacral ligaments can produce severe dysmenorrhea and, if one is to be conservative in one's surgical approach, it is most difficult to know which lesions are producing the pain.

The question of fertility in these patients is most interesting and in many it is the chief symptom which brings them to the gynecologist. What part the endometriosis plays in this is certainly problematical. It is true, however, that 30 to 50 per cent will have a primary sterility problem. In this group of patients 737 were married and in 215 (29.2 per cent) of them there were no pregnancies recorded (Table IV).

It is of interest that in some of these patients infertility develops after 1 or more pregnan-

*15 patients unmarried not included.

cies. For example, only 32 per cent of those becoming pregnant had fewer than 2 live births and 57 per cent became infertile after the delivery of 2 or more children. The reason for this certainly needs careful study and consideration, for it does appear that if one of these patients does become pregnant it may have something to do with subsequent infertility. It is known that 100 per cent of patients who have diffuse uterine adenomyosis (internal endometriosis) have had children, so that perhaps it may be the trauma which causes the endometrial cells to invade the myometrium. When this situation ensues, dysmenorrhea becomes progressively more severe, the uterus becomes usually somewhat enlarged and the patient becomes sterile or aborts when pregnancy occurs. The cure in these cases is hysterectomy.

A word of caution should be expressed concerning the results of conservative operations in an attempt to correct the sterility. Our records show that not more than 10 per cent of those who have been treated surgically will later become pregnant. Therefore, the chances of future pregnancy occurring are probably just as great if the patients are left alone.

The difficulties which surgeons have in doing any pelvic operations where endometriosis predominates are explained on a sound and correct pathologic basis. The endometrium and its stroma cells are among the most rapidly growing and repairing tissues in the body. The stroma cells and the surrounding tissue which they stimulate form dense fibrous adhesions. The tarry material which is periodically spilled into the pelvis contains blood, tissue debris, and glycogen. It is far more ir-

ritating and causes denser and tougher fibrous adhesions than does the inflammatory reaction from specific infections or fecal fistulas. Also the endometrial cells invade the muscular walls of the intestine and the peritoneum overlying the ureters, bladder, and uterus, a fact which accounts for the inability of the surgeon to separate the intestine by any means other than sharp dissection. This fact clearly explains why there is a rather high incidence of fecal fistulas subsequent to surgical intervention for endometriosis.

Given a case of extensive endometriosis with chocolate cysts and uterine fibroids which requires removal of all pelvic organs for a cure, the operation is generally a very difficult procedure and, unless meticulous care is used, complications such as vesicovaginal fistula, ureteral injuries, intestinal fistulas and obstruction will occur. The type of hysterectomy should be a supracervical one because in this disease the paracervical tissues are involved in the endometrial process which has resulted in formation of considerable scar tissue with fixation of the cervix and the lower ends of the ureters. The ureters in this region become fixed to the peritoneum and covered, and if one elects to do a total hysterectomy these structures do not drop away in the usual manner. Injury of a ureter usually takes place about 1 inch (2.5 cm.) above the ureterovesical juncture. One of the most common injuries to the ureter is interference with its blood supply so that a portion of the ureteral wall sloughs out and a ureteral fistula then develops.

There are three other complicating lesions of endometriosis which become surgical problems so that their management must be included in this discussion. The first of these is endometrioma of the urinary bladder. The symptoms are hematuria as well as other symptoms of vesical irritation at the menstrual period.

Cystoscopic examination and a biopsy will reveal the nature of the lesion usually, although not every time. Occasionally the pathologic diagnosis of an inflammatory lesion is made a result which leaves one to wonder if the lesion is a malignant one associated with metastatic implantation. Repeated biopsies

should settle the issue. This is important since the management of these two lesions is entirely different and the prognosis is profoundly different.

An endometrioma, such as of the bladder is an instance of one benign tissue invading a normal tissue. Complete surgical excision cures the patient. However to perform a complete excision is best done when the endometrioma is congested with blood. At this time its extensions can be more easily identified. Many of these endometriomas of the bladder are solitary lesions so that no other surgical treatment on the pelvic organs is required.

Another type of endometrioma which may cause more serious trouble is an endometrioma of the sigmoid. Fortunately, these lesions are not all obstructive and do not all require resection of the bowel. The sigmoid is usually involved in extensive pelvic endometriosis but, if the bowel is not obstructed, the lesion on the bowel will regress with complete removal of the ovarian tissue. But if partial or complete obstruction has already begun then castration alone is not sufficient and one must proceed with colostomy, segmental resection and anastomosis.

Finally, there are some implantation endometriomas other than those in abdominal scars or in the umbilicus which are more difficult to attack surgically. These are the implants which develop in the suture line of the vaginal vault subsequent to vaginal hysterectomy, those that occur in the scar of a repaired perineum and those beneath the bladder where a cystocele had been repaired. These lesions become very troublesome and produce marital disturbance to such a degree that excision of the lesions are necessary. Since the lesions do occur, they cause a simple dilatation and curettage to assume considerable importance if the patient is to undergo vaginal hysterectomy or vaginal repair or if both are to be carried out.

To summarize the surgical treatment of endometriosis briefly, one must conclude that it is much better from every point of view to delay surgical intervention in the disease as long as possible unless it is obvious that one is dealing with a malignant lesion or the uterine

and adnexa which in themselves require surgical treatment. Conservative operations for the relief of dysmenorrhea and menstrual disturbances and the correction of infertility should be undertaken only after careful consideration and a full discussion with the patient, her parents, or her husband, as the case may be. Radical surgical treatment is the most effective means and the end result will be a greater number of satisfied and cured patients.

Surgical procedures in the pelvis for endometriosis are always more difficult than the usual ones, because of the dense fibrous adhesions which it produces. Injury of the intestines, ureters, and bladder is to be avoided by the surgeon having a more complete acquaintance with the nature of endometriosis, and always keeping in mind that this is a specific example of one benign tissue invading another. Complete cure is effected by local excision of solitary lesions or castration in diffuse types.

irritating and causes denser and tougher fibrous adhesions than does the inflammatory reaction from specific infections or fecal fistulas. Also, the endometrial cells invade the muscular walls of the intestine and the peritoneum overlying the ureters, bladder, and uterus, a fact which accounts for the inability of the surgeon to separate the intestine by any means other than sharp dissection. This fact clearly explains why there is a rather high incidence of fecal fistulas subsequent to surgical intervention for endometriosis.

Complete cure is effected by local excision of solitary lesions or castration in diffuse types.

THE RADICAL MASTOIDECTOMY

Anatomical Considerations in Surgical Technique

J BROWN FARRIOR, M D , F A C S , Tampa, Florida

THE present day renaissance in otological surgery is, at a superficial glance, associated only with the endaural incision and the fenestration operation, technical procedures aided by the electrically driven burr and magnification. More careful study of the developmental period of this renaissance will reveal the evolution of sound clinical anatomical knowledge of the temporal bone, accurate to the finest microscopic detail. Attention to this anatomical detail is essential in all otological surgery.

According to Boies, the objective in the radical mastoidectomy is to remove the disease and, thus, the danger to life and to preserve as much hearing as possible. However, the patient will measure the results in terms of a dry ear.

The success of the radical mastoidectomy, as measured by a cured patient with a dry ear with maximum hearing, is dependent upon the minutely accurate surgical technique in the exenteration of the disease and upon the meticulous postoperative care of the cavity. Toward this goal, I want to stress two anatomical considerations in the dissection of the middle ear, to outline the procedure of the radical mastoidectomy, and to advocate the primary skin graft as an aid in facilitating the accurate healing of the mastoid and middle ear cavities.

ANATOMICAL CONSIDERATIONS

Among the many potential minute imperfections in the radical mastoidectomy, which may result in persistent suppuration, are residual foci of infection in the epitympanum, the hypotympanum, and the tympanum proper, including the eustachian tube orifice. In my opinion, the most frequent causes for this persistent suppuration are first, residual disease foci in the hypotympanum and, second, inac-

curate or officious surgery of the tympanic orifice of the eustachian tube. At the onset of this presentation, I want to describe the anatomy of the hypotympanum and the eustachian tube orifice.

Hypotympanum Anatomically, the hypotympanum is bounded externally by the rim of the annulus tympanicus and the infra-annular mass of bone which constitutes the floor of the external auditory canal. As illustrated in Figure 1, this infra-annular mass contains no important structures anterior to the facial nerve. The height of this external wall will vary with the depth and the cellular development of the hypotympanum. In the radical mastoidectomy, this infra-annular mass must be lowered to the level of the depth of the hypotympanum or there will result a hypotympanic pocket. Further, this infra-annular mass must be removed to complete the accurate dissection of the medial wall of the hypotympanum. On the medial wall of the hypotympanum (Fig. 2) are the jugular bulb posteriorly and the carotid artery anteriorly. Together, these structures form a V, in which rests the promontory of the cochlea.

The pneumatization of the hypotympanic cells is highly developed in the anthropoid apes and is rudimentary in man. Inferiorly, the hypotympanic cells are superficial and are easily exenterated after the removal of the infra-annular mass. Posteriorly, the hypotympanic cells may extend medial to the facial nerve and, as pointed out by Almour, are usually responsible for the retrofacial and infralabyrinthine cellular development. Medially, the hypotympanic cells may extend through the V formed by the carotid artery and jugular bulb to pneumatize the petrous apex. Anteriorly, the hypotympanic cells are continuous with the petrotubal cells. In the radical mastoidectomy, these potential routes of cellular development must be explored, even though the mastoid, itself, is sclerotic.

From the Department of Otolaryngology, Tampa Municipal Hospital, Tampa, Florida.

Presented before the Clinical Congress, American College of Surgeons, Los Angeles, California, October 18 to 21, 1915.

The eustachian tube Guilty or not guilty, the eustachian tube has long been "the accused" when persistent suppuration follows an inaccurate radical mastoidectomy. Many articles have been written, describing methods of corking up the eustachian tube, and many instruments have been devised for stenosing of the eustachian tube at the isthmus. In the radical mastoidectomy, all accessible disease must be removed from the tympanic orifice of the eustachian tube. However, with the most thorough dissection, there will invariably remain some inaccessible diseased peritubal cells, granulation tissue, and mucous membrane which, postoperatively, may continue to suppurate or form mucus. If the eustachian tube is patent at the isthmus (Fig 2), this normal mucoid discharge, or any minor suppuration, will continue to flow down its normal channel into the nasopharynx. However, if an attempt is made to cork up the eustachian tube with the tensor tympani muscle or to stenose the eustachian tube at the isthmus with the Jensen or Yankhauer curets, this residual disease will backfire into the middle ear, producing a so called tubal ear. It is, therefore, my practice to exenterate all accessible disease at the tympanic orifice of the eustachian tube but never to attempt to produce a stenosis at the isthmus. A eustachian tube so treated will seal itself at the tympanic orifice.

Fig 2 All accessible disease is removed from the hypotympanum and tympanic orifice of the eustachian tube. Within the eustachian tube, there will invariably remain mucous membrane, granulations, and peritubal cells which will discharge into the nasopharynx if the isthmus is patent.

Fig 1 A sagittal section through the annulus tympanicus reveals the dense area of cancellous bone which forms the floor of the external auditory canal. This "infraannular mass" is the external boundary of the hypotympanum and must be lowered to the level of the depth of the hypotympanum to prevent a pocketing of hypotympanic discharge.

OPERATIVE PROCEDURE

The mastoid cortex is exposed through the incision of the operator's choice. It may be postauricular or endaural. The endaural approach is now generally preferred because of its simplicity, the direct avenue of approach to the antrum and middle ear, the minimal bleeding, the perfect orientation, the minimal trauma to the soft parts, the improved exposure of the tympanum, the absence of trauma to the cartilages, the free postoperative drain-

Fig 3 The endaural incision (as illustrated A, B, C, - A, D) preserves the skin of the canal, prevents stenosis of the canal, protects the margin of the conchal cartilage and aids in epithelization. The dotted line indicates the margin of the conchal cartilage, it is not an incision.

THE RADICAL MASTOIDECTOMY

Anatomical Considerations in Surgical Technique

J. BROWN FARRIOR, M.D., F.A.C.S., Tampa, Florida

THE present day renaissance in otological surgery is, at a superficial glance, associated only with the endaural incision and the fenestration operation, technical procedures aided by the electrically driven burr and magnification. More careful study of the developmental period of this renaissance will reveal the evolution of sound clinical anatomical knowledge of the temporal bone accurate to the finest microscopic detail. Attention to this anatomical detail is essential in all otological surgery.

According to Boies, the objective in the radical mastoidectomy is to remove the disease and, thus, the danger to life and to preserve as much hearing as possible. However, the patient will measure the results in terms of a dry ear.

The success of the radical mastoidectomy, as measured by a cured patient with a dry ear with maximum hearing, is dependent upon the minutely accurate surgical technique in the exenteration of the disease and upon the meticulous postoperative care of the cavity. Toward this goal I want to stress two anatomical considerations in the dissection of the middle ear: to outline the procedure of the radical mastoidectomy, and to advocate the primary skin graft as an aid in facilitating the accurate healing of the mastoid and middle ear cavities.

ANATOMICAL CONSIDERATIONS

Among the many potential minute imperfections in the radical mastoidectomy, which may result in persistent suppuration, are residual foci of infection in the epitympanum, the hypotympanum, and the tympanum proper including the eustachian tube orifice. In my opinion, the most frequent causes for this persistent suppuration are first residual disease foci in the hypotympanum and, second, inaccurate or officious surgery of the tympanic orifice of the eustachian tube.

At the onset of this presentation, I want to describe the anatomy of the hypotympanum and the eustachian tube orifice.

Hypotympanum. Anatomically, the hypotympanum is bounded externally by the rim of the annulus tympanicus and the infra-annular mass of bone which constitutes the floor of the external auditory canal. As illustrated in Figure 1, this infra-annular mass contains no important structures anterior to the facial nerve. The height of this external wall will vary with the depth and the cellular development of the hypotympanum. In the radical mastoidectomy, this infra-annular mass must be lowered to the level of the depth of the hypotympanum or there will result a hypotympanic pocket. Further, this infra-annular mass must be removed to complete the accurate dissection of the medial wall of the hypotympanum. On the medial wall of the hypotympanum (Fig. 2) are the jugular bulb posteriorly and the carotid artery anteriorly. Together, these structures form a V, in which rests the promontory of the cochlea.

The pneumatization of the hypotympanic cells is highly developed in the anthropoid apes and is rudimentary in man. Internally the hypotympanic cells are superficial and are easily exenterated after the removal of the infra-annular mass. Posteriorly, the hypotympanic cells may extend medial to the facial nerve and, as pointed out by Altmour, are usually responsible for the retroaural and infra-labyrinthine cellular development. Medially the hypotympanic cells may extend through the V formed by the carotid artery and jugular bulb to pneumatize the petrous apex. Anteriorly, the hypotympanic cells are continuous with the peritubal cells. In the radical mastoidectomy, these potential routes of cellular development must be explored even though the mastoid, itself, is sclerotic.

From the Department of Otolaryngology, Tampa Municipal Hospital, Tampa, Florida.
Read at the 11th Annual Meeting of the American College of Surgeons, St. Louis, Missouri, October 15, 1955.

The eustachian tube Guilty or not guilty, the eustachian tube has long been "the accused" when persistent suppuration follows an inaccurate radical mastoidectomy. Many articles have been written, describing methods of corking up the eustachian tube, and many instruments have been devised for stenosing of the eustachian tube at the isthmus. In the radical mastoidectomy, all accessible disease must be removed from the tympanic orifice of the eustachian tube. However, with the most thorough dissection, there will invariably remain some inaccessible diseased peritubal cells, granulation tissue, and mucous membrane which, postoperatively, may continue to suppurate or form mucus. If the eustachian tube is patent at the isthmus (Fig 2), this normal mucoid discharge, or any minor suppuration, will continue to flow down its normal channel into the nasopharynx. However, if an attempt is made to cork up the eustachian tube with the tensor tympani muscle or to stenose the eustachian tube at the isthmus with the Jensen or Yankhauer curets, this residual disease will backfire into the middle ear, producing a so called tubal ear. It is, therefore, my practice to exenterate all accessible disease at the tympanic orifice of the eustachian tube but never to attempt to produce a stenosis at the isthmus. A eustachian tube so treated will seal itself at the tympanic orifice.

Fig 2 All accessible disease is removed from the hypotympanum and tympanic orifice of the eustachian tube. Within the eustachian tube, there will invariably remain mucous membrane, granulations, and peritubal cells which will discharge into the nasopharynx if the isthmus is patent.

Fig 1 A sagittal section through the annulus tympanicus reveals the dense area of cancellous bone which forms the floor of the external auditory canal. This "infra-annular mass" is the external boundary of the hypotympanum and must be lowered to the level of the depth of the hypotympanum to prevent a pocketing of hypotympanic disease.

OPERATIVE PROCEDURE

The mastoid cortex is exposed through the incision of the operator's choice. It may be postauricular or endaural. The endaural approach is now generally preferred because of its simplicity, the direct avenue of approach to the antrum and middle ear, the minimal bleeding, the perfect orientation, the minimal trauma to the soft parts, the improved exposure of the tympanum, the absence of trauma to the cartilages, the free postoperative drain-

Fig 3 The endaural incision (as illustrated A, B, C, - A, D) preserves the skin of the canal, prevents stenosis of the canal, protects the margin of the conchal cartilage and aids in epithelization. The dotted line indicates the margin of the conchal cartilage, it is not an incision.

Fig 4 Direct approach to mastoid antrum, with simultaneous removal of cortex of outer two thirds of posterior superior bony walls of external auditory canal and neighboring mastoid cortex, performed with burrs or with gouge

Fig 5 Demonstrates the internal landmarks of the sclerotic mastoid cavity, with the cortex removed. Note the relative superior position of the mastoid antrum to the external auditory canal

age, the ease of postoperative dressing, and the reduced period of hospitalization

Hoople, Lathrop, Tolan, and others have modified the Shambaugh (11) incision, preserving the skin of the canal and removing the subcutaneous mass of tissue and periosteum. I prefer this modified incision, believing that the preservation of the flap aids in preventing stenosis of the external auditory canal and facilitates the epithelization of the cavity.

The incision is begun at 12 o'clock, deep in the external auditory canal. At the same depth in the canal, the incision is carried from 12 o'clock around the posterior rim of the canal to 7 o'clock (right ear, 5 o'clock in left ear). The incision is then downward and outward to the rim of the cyma concha. The second incision begins at the original point, 12 o'clock, and is carried vertically upward through the periosteum to the rim of the temporal muscle and then superficial to the temporal muscle, between the helix and the tragus, as in the Lempert (7) incision. The skin and periosteum are then elevated from the cortex of the outer one-third of the bony wall of the external auditory canal and the mastoid. The pedicle, thus created, is grasped at its inner extremity with an Allis forceps and the epithelium elevated from the subcutaneous tissue. The subcutaneous tissue, excised along the margin of the conchal cartilage and the inferior border of the temporal muscle, is discarded. The epithelium preserved as a flap covers the rim of the conchal cartilage and pre-

vents stenosis of the auditory canal. This incision is little more than the endaural modification of the classic Koerner flap.

The inner one-third of the cutaneous lining of the external auditory canal is then reflected from the bony wall, the notch of Rivinus and the posterosuperior limit of the annulus tympanicus (as with the fenestration flap). In this way, the surgeon is immediately oriented as to the depth of the epitympanum, the annulus, and, thereby, the depth of the facial nerve.

The mastoidectomy. Regardless of the incision used, the mastoidectomy begins with the direct approach to the mastoid antrum. The cortex of the posterosuperior bony canal wall and the adjacent mastoid are removed simultaneously to gain direct access into the mastoid antrum (Fig 4). This bone may be removed with the electrically driven burr, as utilized by Lempert (6), or with the gouge and mallet. With this direct approach into the mastoid antrum (Fig 5), the operator is always oriented in relation to important internal landmarks, the rim of the annulus tympanicus identifies the depth of the vertical course of the facial nerve, and, immediately upon entering the antrum, the operator can identify the external surface of the horizontal semicircular canal. Thus oriented, the operator eviscerates all disease in the mastoid. The cortex is removed from the mastoid tip only to the extent which is necessary to uncover any tip cells or to bring the level of the inferior surface of the antrum down to the level of the

inferior surface of the external auditory canal Trautman's angle is explored, and all disease external to the superior semicircular canal removed. A sclerotic mastoid tip is not disturbed. In the usual chronic disease of the ear, this exteriorization and exploration of the antrum and periantral region constitute the limit of the mastoidectomy. If the medial surface of the antrum is found to be lined with the matrix of a cholesteatoma, this squamous epithelium is not disturbed.

This direct approach into the mastoid antrum discards the long taught technique of performing a simple mastoidectomy before beginning the removal of the bony wall of the auditory canal. It thereby minimizes the danger of injury to the sigmoid sinus. Further, with the immediate identification of the horizontal canal and antrum, the inexperienced operator is less likely to create a false antrum below the canal or transect the vertical course of the facial nerve. Figure 5, the drawing of specimen 2, illustrates the high position of the mastoid antrum relative to the auditory canal.

Tympanectomy The dissection of the tympanic cavity is divided into the dissection of the epitympanum, dissection of the hypotympanum, and the dissection of the tympanum proper, including the eustachian tube orifice. The dissection of the epitympanum is begun with the removal of its external wall. This simultaneous removal of the external wall of the epitympanum and thinning of the bridge will bring into view the incus and the head of the malleus. The incus or its remnants are removed at the earliest convenience. The external wall of the epitympanum is removed well anteriorly to exteriorize the anterior cul-de-sac of the epitympanum completely. The entire expanse of the bridge (the inner superior wall of the external auditory canal over the notch of Rivinus) is thus brought into view. The thinned arch of the bridge is removed with the Lempert rongeur (Fig 6), the initial bite being taken well anteriorly to avoid injury to the facial nerve. The posterior buttress of the bridge (Stacke's spine) is left in position until the final stages of the operation to protect the footplate of the stapes and the facial nerve. The anterior buttress of the bridge and the remaining external wall of the

Fig 6 The epitympanic dissection begins with the removal of the external wall of the attic and the narrowing of the bridge. Here, the arch of the bridge has been removed. The anterior buttress of the bridge is next removed to permit the epitympanic dissection. The posterior buttress of the bridge is left in position until the final stages of the operation to protect the peristapedial area.

attic is now removed anteriorly to the plane of the anterior limit of the anterior wall of the external auditory canal (Fig 7). The malleus or its remnants are removed. The medial wall of the epitympanum is explored from behind, forward. With the face of a small mastoid curet directed medially, the mucous membrane is dissected off the ampulla of the horizontal semicircular canal, and this dissection is carried downward and forward off the ampulla to identify the cochleariform process of the tensor tympani muscle. From this point, the dissection is then carried downward and backward, and the entire intratympanic course of the facial nerve delineated (Fig 7). The nerve, so identified, may be avoided. With the intratympanic course of the facial nerve identified, all remaining disease in the epitympanum is exenterated.

Dissection of the hypotympanum Dissection of the hypotympanum requires an additional incision, the removal of the annulus and the infra-annular mass, and the exenteration of the hypotympanic disease. With an angulated canal knife, an incision is made through the skin and periosteum, 5 millimeters external and parallel to the annulus tympanicus, in a manner similar to the Lempert (8) incision for the tympanosympathectomy. This 5 millimeters of epithelium and the remaining fibro-

Fig 7 The completed radical mastoidectomy reveals the exenteration of all disease in the tympanic and mastoid cavity, with delineation of all the internal landmarks of the middle ear and mastoid

cartilaginous ring of the annulus tympanicus are then dissected free to permit direct visualization of the annulus. The remaining inner cutaneous lining of the auditory canal, the free fibrocartilaginous ring of the annulus, the remnants of the tympanic membrane, and the free excess of granulations are then removed from the tympanic cavity. Before the detailed dissection is continued, a pledget of epinephrine is placed in the tympanic cavity to secure hemostasis, this procedure may be repeated from time to time to permit accurate visualization. When a dry field has been obtained, the inferior portion of the annulus tympanicus and the underlying infra-annular mass of bone (Fig 1) are removed to the level of the floor of the hypotympanum with the large polishing burr. The polishing burr is preferred, as it is easily controlled and is less likely to engage any fragments of tissue. The burr should rotate in an anterior direction (clockwise in the right ear and counterclockwise in the left ear) to avoid running in the direction of the stapes. With the hypotympanum thus exteriorized, the mucous membrane and granulation tissue is dissected from below, upward, off the medial wall of the hypotympanum, delineating the jugular bulb posteriorly and the carotid artery anteriorly (Fig 2). The potential routes of cellular extension are explored, and infection removed. The end result is a wide open hypotympanum with all accessible disease removed.

Dissection of the tympanic cavity and eustachian tube The dissection of the tympanum proper is begun with the removal of infected tissue from the promontory. This is carried forward to exenterate the disease in the eustachian tube orifice and, finally, posteriorly to the peristapedial area.

The exenteration of the tympanic disease is begun at the cochleariform process. As the dissection is carried anterior to the cochleariform process, the mucous membrane and granulation tissue are elevated from the external and inferior surfaces of the semicanal of the tensor tympani muscle (Fig 7). The dissection is carried downward, off the anterior surface of the promontory and then anteriorly, well into the orifice of the eustachian tube. Then, as the dissection is continued upward from the hypotympanum, the mucous membrane, granulations, and the tympanic plexus are elevated from the promontory of the cochlea and, again, the dissection carried well forward into the orifice of the eustachian tube. The resultant aggregation of tissue in the orifice of the eustachian tube is grasped with the aural biting forceps and avulsed from the depth of the tubal orifice. All accessible disease is then removed from the eustachian tube orifice with a small mastoid curet and aural biting forceps. The dissection is carried well into the eustachian tube, however, no attempt is made to produce a stenosis at the isthmus. Nor is an unaffected tensor tympani muscle ever disturbed.

Throughout the operation, the peristapedial area has been protected by a relatively high facial ridge and by the posterior buttress of the bridge (Stacke's spine). The facial ridge (posterior bony wall of the external auditory canal) is now lowered to the external surface of the horizontal semicircular canal (Fig 7). In the performance of this maneuver of lowering the facial ridge, the burr should rotate in a posterior direction (counterclockwise in the right ear, clockwise in the left ear) so that the burr will never run into the middle ear to produce irreparable damage. The lowering of the facial ridge will thin the posterior buttress of the bridge from without, inward, to the point of spontaneous fracture. The final removal of the posterior buttress exposes the peristapedial

area Infected granulation tissue around the stapes and the oval window is removed, the dissection always being from posteriorly, anteriorly, in the long axis of the footplate of the stapes to obtain maximum utilization of the fixing or guy-wire effect of the stapedius muscle (Fig 7) Any infected granulation tissue is removed from area of round window

This minute dissection of the peristapedial area is carried out only when this area is involved with infected granulation tissue If the peristapedial area is lined with a relatively healthy mucous membrane or with the lining matrix of a cholesteatoma, this thin epithelium is always preserved The preservation of such epithelium will result in minimum postoperative scarring in the peristapedial area and maximum postoperative mobility of the footplate of the stapes As Meltzer and Baron have pointed out, the preservation of such epithelium will result in maximal postoperative preservation of hearing

Summary of radical mastoid technique The end result of the tympanomastoid dissection should be a perfectly dry cavity with no remaining granulation tissue Posteriorly, the mastoid antrum and air cells have been explored and all disease exenterated The cortex of the mastoid tip has been lowered to the level of the floor of the external auditory canal or to the inferior limit of the residual mastoid tip cells The sclerotic portion of the mastoid tip has not been disturbed Superiorly, the overhanging mastoid cortex has been removed to the level of the tegmen of the middle cranial fossa Anteriorly, the external wall of the attic and the bridge have been removed to the anterior limit of the anterior cul-de-sac of the epitympanum Inferiorly, the floor of the bony wall of the external auditory canal (the infra-annular mass) is lowered to the depth of the hypotympanic cells Medially, the facial ridge (the posterior bony wall of the external auditory canal) has been lowered to the level of the external surface of the horizontal semicircular canal With the tympanic cavity thus exteriorized, all granulation tissue and disease have been removed from the tympanic cavity and eustachian tube orifice The exteriorized mastoid cavity and middle ear will then receive a primary skin graft

Fig 8 The entire radical mastoid cavity has been lined with the primary skin graft. The skin flap is turned over the margin of the conchal cartilage The upper two-thirds of the vertical incision is closed with two vertical mattress sutures The skin graft is sutured to the anterior margin of the lower one third of the vertical incision The skin graft and rayon are held in position with synthetic sponge packing

PRIMARY SKIN GRAFT

The meticulous postoperative care of the radical mastoidectomy is as essential to a good result as is the accurate and thorough exenteration of disease The goal of this postoperative care is to secure a healed radical mastoid cavity which resembles in shape the postoperative bony cavity and is covered with the thinnest possible epithelium, particularly in the region of the oval and round windows The primary skin graft is an aid in attaining this goal, through more rapid healing, reducing the possibility of annoying granulation tissue and stenosis of the cavity, and, in reducing the postoperative cicatrization in the peristapedial area

The skin graft is taken prior to the mastoidectomy to avoid contamination of the donor site and the necessity of a second sterile operative setup During mastoidectomy, the skin is preserved in normal saline and, at completion of the mastoidectomy, strips of skin are cut in a pattern to dress the operative cavity

Instruments The instruments for obtaining a good otological skin graft consist of the Weck razor and an appropriately shaped skin traction block The Weck razor is preferred to any other type of dermatome or skin graft knife because of the sharp, expendable blades Skin traction blocks are notched to the width of the

blade to provide an elevated flat donor site with depression of the adjacent skin

Technique After being surgically prepared, the donor site is thoroughly greased with sterile vaseline. The right skin traction block is held in fixed position by the assistant, the left skin traction block is held in the operator's left hand with the blade flat against the donor site. The operator follows the progress of the left skin traction block with gentle to and fro movements, adjusting the thickness of the skin to his individual preference. Eliminating all cumbersome equipment, this simple technique provides a thoroughly adequate otological skin graft.

Application When the mastoidectomy is nearing completion, the surgical nurse spreads the skin on wet surgical rayon, with the cut surface up. The skin and the rayon are then cut to a pattern to fit the mastoid cavity. The rayon backing makes the skin more manageable. It is my practice to cut three strips (A, B, and C) to be applied to the cavity. Section A covers the medial wall of the tympanum, the hypotympanum, and the denuded auditory canal. Section B covers the facial ridge, the medial wall of the antrum, and the sigmoid sinus plate. Section C covers the epitympanum, the tegmen, the temporal muscle, and the lower one-third of the vertical incision. As each section is placed over its individual area, it is anchored in position with a small pledget of synthetic sponge and the long free end of the rayon is brought out of the auditory canal to provide further fixation. The thinnest available portion of the skin is selected to line the medial wall of the tympanum. Its free border is placed adjacent to, but never over, the oval and round window. This free border of skin provides an island from which the thinnest possible layer of epithelium can grow to cover the oval and round windows. The incision is closed as illustrated in Figure 8.

Postoperative care The synthetic sponge and rayon are removed at the end of the first postoperative week. The cavity may then be treated as the surgeon desires, I prefer repacking at weekly intervals for 3 weeks. One-half inch gauze, soaked in furacin, is used for packing. The bacteriostatic action of the furacin will usually permit the packing to remain in

position for 7 days. The epithelial debris may be wiped away at the end of the second, third, and fourth postoperative weeks. If the cavity has been well lined with skin, epithelization will be nearly complete at the end of the fourth postoperative week. Thereafter, one may adopt dusting powder, gentian violet, or drops until healing is complete.

COMMENT

The success of the radical mastoidectomy is dependent upon the minutely accurate enteration of the tympanic and mastoid disease and upon meticulous postoperative care of the radical mastoid cavity. The completed radical mastoidectomy should consist of the exteriorization of all pockets of infection and the enteration of all accessible disease. The postoperative care of the radical mastoidectomy is greatly facilitated by the primary skin graft.

SUMMARY

1 Sound anatomical knowledge has been the basis for the present renaissance in otological surgery.

2 The minute anatomy of the hypotympanum, the eustachian tube and tympanic cavity have been reviewed in reference to the radical mastoidectomy.

3 The technique of the radical mastoidectomy has been outlined.

4 The primary skin graft is advocated to facilitate complete postoperative healing of the radical mastoid cavity.

5 The technique of skin grafting is outlined.

THE SUCTION SOCKET FOR ABOVE-KNEE AMPUTEES

PAUL E. McMASTER, M D , F A C S , and ROBERT MAZET, Jr , M D , F A C S ,
Los Angeles, California

THE suction socket prosthesis for above-knee amputation eliminates pelvic band and shoulder harness. The special construction and fitting cause it to be held on to the stump by a moderate amount of suction. The authors have had an opportunity to observe the fitting and use of more than 60 suction socket prostheses during the training and experimental programs of The Committee on Artificial Limbs of the National Research Council and Veterans Administration, plus observations on private patients.

Observations indicate that the suction socket compared to the conventional leg is less cumbersome, allows a greater range of mobility, feels more like an integral part of the patient, and offers less interference with clothing.

In 1863 Parmelee of New York obtained the first known patent on the suction socket. Subsequent patents were issued to Beacock and Sparham of Ontario, Canada, in 1885, to Toles of Stockton, California, in 1911, and to Underwood of Birmingham, England, in 1926.

Following the first World War, several groups in England employed the suction socket with variable results. However, use of the suction socket in England has been dormant for a number of years but has been revived recently. In Germany the suction socket was made and used to some extent following World War I, but it was not popularized until a satisfactory valve was devised in 1932. Since that time, and especially during the recent war, it has been used for many above-knee amputations.

The Surgeon General of the United States Army sent a commission to Europe in 1946 to study the various aspects of amputations and prostheses. The recommendations of this

commission¹ were acted upon by the Advisory Commission on Artificial Limbs of the National Research Council, which instituted in this country a program, in collaboration with the Veterans Administration, to investigate the use and development of the suction socket.

A national suction socket training program for training of surgeons and limb fitters was implemented by the Committee on Artificial Limbs of the National Research Council and the Veterans Administration. The initial school was held at the University of California, Berkeley, California, November 19, 20, 21, 1947, under the direction of Professor Howard D. Eberhard and Doctor Verne T. Inman. Subsequently, schools were held at various centers throughout the country under the auspices of the Veterans Administration and the Orthopedic Appliance and Limb Manufacturers Association. Completion of the specified work offered in these schools resulted in the certification by the Veterans Administration and the Orthopedic Appliance and Limb Manufacturers Association of surgeons as qualified under the Veterans Administration Experimental Suction Socket Program, and certification of limb fitters for the manufacturing and fitting of suction sockets under the same program.

The Veterans Administration and various certified limb fitters are now conducting a continuing experimental suction socket program. Under it carefully selected and supervised patients at several centers have been, and are being, furnished suction sockets. These patients are studied and followed carefully.

¹The Commission was composed of the following:
Colonel Leonard T. Peterson, MC, Chief of Amputation and Prostheses Unit, Surgeon General's Office.
Doctor Paul E. Klopsteg, Chairman, Committee on Prosthetic Devices, National Research Council.
Lt. Colonel Rufus Alldredge, MC, Chief of Amputation Section, England General Hospital, Atlantic City, New Jersey.
Mr. Edmond M. Wagner, Executive Assistant, Committee on Prosthetic Devices, National Research Council.
Lt. Colonel Robert J. F. Lewis, Ordnance, Amputation and Prostheses Unit, Surgeon General's Office.
S/Sgt. John Paul Gavell, Recorder.

From the Orthopaedic Service, U. S. Veterans Hospital (Wadsworth General Hospital), Los Angeles, California, and U. S. Veterans Administration Regional Office, Prosthetic Division, Los Angeles, California.

As a result of this program, some alterations of the suction socket have already been found advisable and others are being studied

The characteristic features of the suction socket are

1 Pelvic bands and shoulder harness are eliminated (Fig 1)

2 The muscles of the stump control all movements

3 The socket is held on by a moderate negative pressure, which requires an accurate and snug fit, but without undue pressure

4 Stump socks are eliminated

5 Body weight is taken mainly on the ischial tuberosity. Some side bearing appears to be advantageous. In a few instances partial end bearing is tolerated

6 The socket is applied by using a thin sock on the stump. This is pulled off and out through the valve opening at the distal end

which pulls the stump into the socket. Body weight is then applied and the valve is screwed in, and the socket thus sealed

Instruction in proper walking, muscle control, and posture are important to eliminate or reduce limp, unsightly gait, and lordosis

The indication for a suction socket leg is a good thigh stump. The minimal length of stump is considered to be $4\frac{1}{2}$ to 5 inches measured from the adductor tubercle to bone end. Shorter stumps require a pelvic band or shoulder strap

The main contraindications are

1 Large scars which are either painful or adherent over a prominent end. Extensive scars which are located at upper end of socket may cause loss of suction. These conditions however can be corrected surgically

2 Osteomyelitis, unless it has been definitely arrested

3 Large tender bony spurs. These, however, can be eliminated surgically

4 Extensive skin disease. A dermatologist, however, can correct many of these conditions

5 Capillary fragility and purpuric conditions, characterized by persons who bruise easily have been considered as contraindications but recently patients have been fitted successfully

6 Unco-operative or mentally deficient patients

Peripheral vascular disease has been considered a contraindication, but a few cases of Buerger's disease in younger individuals have been successfully fitted

Bilateral above-knee amputees have been fitted satisfactorily with suction sockets, although one in the authors' series has not been successful as the patient is unable to put on the prostheses without aid

The construction of the socket is from pre cut patterns. Willow wood is considered to be the most adaptable material for making the socket, as it can be reshaped easily to changing size of the stump. The socket can be made smaller by the addition of a liner or enlarged by cutting out. Plastic material should not be used for the initial construction, but may be used later when the person becomes expert with the suction socket and the stump has stabilized in size

Fig 2 Top view of suction socket prosthesis, *a*, ischial seat, *b*, gluteal channel, *c*, protuberance behind trochanter, *d*, adductor channel, *e*, valve opening

The following points of construction are emphasized (Figs 2 and 3)

1 Medially a channel is cut out for the adductor muscles. The height is determined by individual variations and comfort, being approximately the same as the ischial seat.

2 Anteriorly, the fit is snug but not tight enough to cause compression on the femoral vessels. If too high it causes pressure in sitting. The upper and inner portion of the socket is often slightly undercut approximately $\frac{1}{2}$ inch below the top with a long taper in order to hold suction.

3 Laterally, the socket is made higher, almost to the tip of the trochanter. If too high it tends to obstruct abduction. A protuberance is left immediately in back of the trochanter which is of great benefit in assisting with rotation and stability.

4 Posteriorly, a cut-out is made for the gluteus maximus. The ischial seat is of utmost importance and specific details, such as height, size, shape, and incline, must be carefully individualized.

5 One or 2 inches of free space in the socket at the end of the stump is desirable to allow for installation of the valve.

6 A screw-type automatic expulsion valve, allowing a small exchange of air, is now generally used. It is placed at the distal end of the socket and preferably not in contact with the skin. It should be in an acces-

Fig 3 Side view of suction socket prosthesis, *a*, ischial seat, *b*, gluteal channel, *c*, protuberance behind trochanter, *d*, adductor channel, *e*, valve opening

sible place for the patient to remove the thin sock in pulling the stump into the socket, as well as for manual control of the valve. A negative pressure of $1\frac{1}{2}$ pounds per square inch during the swing phase of walking and $\frac{1}{2}$ pound of positive pressure during the stance phase are considered sufficient. Greater pressures are in general undesirable and can be regulated by valve corrections.

7 Several different types of finish have been used but in general cellulose acetate has been most satisfactory.

Mistakes in construction which must be avoided are

1 An ischial seat which is either too high or too deep, or prolonged too far medially causing adductor constriction and pressure on ramus. An ischial seat having too much undercut causing stretching of skin over its sharp border and pressure on sitting.

2 The gluteal channel cut too narrow causing undue pressure.

3 Too tight a fit, anteriorly, causing pressure on femoral vessels with subsequent edema of stump, and interference with flexion.

4 A socket cut too high or narrow medially causing adductor pressure.

5 A socket cut too high laterally limiting abduction

6 Too much vacuum, or negative pressure
Complications, if present, generally arise because of improper selection of cases and inadequate attention to details of construction. Pressure spots can generally be relieved by minor reshaping. Edema, which is not an uncommon complication, is usually due to either too much negative pressure or excessive pressure over the femoral vessels anteriorly or an extremely tight fit of the stump. Either can, as a rule, be corrected easily. Excessive perspiration may occur. A small amount of silica gel placed in the bottom of the socket usually will control this.

Ischial irritation has been the most troublesome feature of the suction socket. Careful fitting and reshaping as well as perseverance on the part of the patient are necessary to overcome this.

It has been noted that during the early stages of wearing a suction socket shrinkage of the stump is apt to occur. This is frequently followed by hypertrophy. One wearer has

increased his stump circumference $5\frac{1}{2}$ inches, and is wearing his seventh socket. Hypertrophy apparently occurs in the muscular tissues from their active use in control of the prosthesis.

Success of the suction socket depends largely on the whole-hearted co-operation of the surgeon, patient, and limb fitter, with frequent consultations during fitting, and as needed whenever difficulties arise.

SUMMARY AND CONCLUSIONS

The suction socket prosthesis has by accumulated evidence, both in this country and abroad, proved to be most satisfactory in the majority of selected cases of above-knee amputation. The most important features are the following:

- 1 Elimination of pelvic bands and shoulder harness
- 2 Easier control of prosthesis and greater ranges of motion
- 3 A feeling that the prosthesis is an integral part of the wearer
- 4 Less interference with clothing

THE EFFECT OF MODERATE DEGREES OF DICUMAROL-INDUCED HYPOPROTHROMBINEMIA ON EXPERIMENTAL INTRAVASCULAR THROMBOSIS

J FORBES ROGERS, M D, RAYMOND J BARRETT, M D, and
CONRAD R LAM, M D, F A C S, Detroit, Michigan

THE drug dicumarol is being used extensively in attempts to prevent or inhibit intravascular thrombosis. Surgeons have employed it as a prophylactic measure against postoperative thrombosis and embolism, as a therapeutic agent in established deep phlebitis of the lower extremities and more rarely as an adjunct in certain operations on blood vessels. Internists have been particularly interested in its possible effect on the incidence of thromboembolic complications in acute myocardial infarction.

There is no doubt that dicumarol exerts a powerful effect on the coagulation mechanism if it is given in sufficient quantities to produce a marked depression of the prothrombin level. In an early experimental study, Dale and Jaques demonstrated a reduced incidence of thrombosis in the traumatized veins of dicumarolized dogs. However, it is little wonder that clotting was inhibited because so much dicumarol was administered (10 mgm per kilogram) that the prothrombin time was above 100 seconds at the time of the test in all of the animals, and it frequently exceeded 200 seconds, indicating prothrombin percentages well below 1 per cent.

In like manner, in the study of Richards and Cortell, extreme degrees of hypoprothrombinemia were produced in a small series of dogs. The prothrombin times of their 4 dogs varied from 171 to 491 seconds, the injection of monolate solution into veins produced less thrombosis than in the controls, but all of the animals subsequently died of hemorrhage.

Thill, Stafford, Spooner and, Meyer produced experimental thrombosis by injecting 0.25 cubic centimeter of monolate solution into the radial veins of dogs. Fifteen animals were given a single dose of dicumarol, 5 milligrams per kilogram and 2 days later, the sclerosing solution was injected. At this time, the prothrombin time varied from 5 to 46.5 seconds (median 18.5 seconds). About a week later, the veins were removed for histologic study. Only 2 veins (6.6 per cent) showed definite thrombosis as compared with an incidence of 50 per cent thrombosis in the controls. No excessive bleeding was encountered at the operation and no postoperative hemorrhage was noted. Hence, they were able to conclude that a definite reduction in the incidence of thrombus formation was noted in dogs previously treated with dicumarol in a dosage equivalent to a therapeutic and safe quantity commonly administered to human beings. Their data could be assumed to provide at least a partial answer to the question which is posed by the title to this communication.

Kieswetter and Shumacker carried out a study of the comparative efficacy of heparin and dicumarol in the prevention of experimental arterial and venous thrombosis. The arteries were traumatized by a deliberately careless suture of incisions into the vessels, the veins were injected with sodium morrhuate. In their control group of 9 animals, thrombosis was present in 92.9 per cent of the femoral arteries, 66.7 per cent of the carotid arteries, and 85.2 per cent of the veins. With heparin administration, they reduced these percentages to 6.7 per cent, 9.5 per cent, and 56.3 per cent respectively. In 10 animals treated with dicumarol before and after operation (prothrombin levels kept below 30 per

From the Division of General Surgery of the Henry Ford Hospital Detroit Michigan

Fig 1 Veins removed from 2 animals 2 days after trauma. The radial veins (on left) are thrombosed, the long saphenous veins (middle) are thrombosed, and the short saphenous veins (right) are free of thrombosis, although it is obvious that the intima has been damaged.

cent of normal), thrombosis occurred in 50 per cent of the femoral arteries, 15.8 per cent of the carotid arteries and 41.4 per cent of the veins.

This inhibition of thrombosis had its price in the form of hemorrhagic complications, however. Of 35 animals treated with heparin, 25 or 71.4 per cent had subcutaneous hemorrhage, there were 19 large hematomas. Nine animals (25 per cent) actually died of hemorrhage. Of 25 dogs treated with dicumarol, 11 or 44 per cent bled subcutaneously. There were 5 large hematomas and 3 deaths from hemorrhage. It is doubtful if a clinical surgeon would be willing to contend with such a complication and mortality rate in order to obtain the possible beneficial anticoagulant effect of either drug.

Most of those who have recommended the use of dicumarol clinically have indicated that they are satisfied with very conservative doses of the drug, so that hemorrhagic complications are minimized. Peters, Guyther, and Brambel tried to keep the prothrombin level in their 50 cases of coronary occlusion between 35 and 50 per cent of normal. Glueck, Strauss, Pearson, and McGuire preferred a level between 20 and 30 per cent. The American Heart Association is carrying out a controlled clinical study of the use of dicumarol in acute myocardial infarction. The instructions to co-operating clinics state that the administration of dicumarol should be discontinued if the prothrombin time goes to

Fig 2 Empiric curves used to convert Quick prothrombin time values to percentage values.

35 seconds. This would represent about 20 per cent of normal. Preliminary reports from this study (exhibit at American Medical Association, 1948) indicate that the drug has a valuable effect in preventing thromboembolic complications. However, in this connection it must be mentioned that at least one clinician (2) prefers that his patients with acute coronary occlusion have a normal prothrombin level, and he administers vitamin K therapy to this end.

The present study was undertaken to study the effect on experimental intravascular thrombosis if dicumarol is administered so as to produce an effect comparable to that commonly sought in human cases, i.e., so that the prothrombin level is in the range of 10 to 30 per cent of normal.

It was elected to use traumatized veins as the experimental lesion to produce thrombosis. The technique was identical with that used by Murray, Jaques Perrett, and Best in their investigation of the effect of heparin. The dogs were anesthetized with intravenous nembutal. A surgical incision was made parallel to but a short distance away from, the vein to be tested. A round curved needle bearing a heavy silk thread was passed into the lumen of the vein for a distance of 2½ centimeter and then out again. The length of vessel con-

taining the suture was then crushed with an artery forceps in three planes. Reasonably uniform trauma to the intima was assumed since the same clamp was used throughout the study and it was always clamped to the first notch. After the crushing, the silk was withdrawn from the vein. Bleeding from the holes made by the needle was negligible. Two days later, the incisions were opened and the veins were inspected for evidence of thrombosis. Patency was determined by cutting across the vein proximal to the crushed area, after which the entire segment was resected and opened (Fig 1).

Six veins on each animal were used. These were the radial, long, and short saphenous veins on the two sides. For the control series, the three veins on the animals' right were traumatized. This series comprised 41 animals or a total of 123 veins. The radial vein was found to be thrombosed 29 times, the long saphenous 37 times, and the short saphenous 31 times. Thus, 97 out of 123 veins were thrombosed, an incidence of 78.8 per cent.

Numerous determinations of prothrombin levels as well as coagulation times were carried out before and during dicumarol administra-

tion The prothrombin method was that of Quick, using a commercial preparation of thromboplastin. For the conversion of time values to percentage values, empiric curves were constructed from the prothrombin time values obtained from testing known dilutions of dog plasma (Fig. 2). Several batches of thromboplastin gave normal prothrombin time values varying from 7.5 seconds to 10.5 seconds. The same thromboplastins gave values on human plasma varying from 13 seconds to 17 seconds. The coagulation time of the blood was determined by a modification of the Lee and White method. Several cubic centimeters of blood were placed in 3 Wassermann tubes. One of the tubes was inverted at 30 second intervals until the clot retained its position in the bottom of the tube, after

which the second tube and, finally, the third tube were inverted until clotting was seen to take place.

Following the control study, dicumarol was administered by mouth (mixed in meat) until the desired prothrombin level was obtained, after which the three veins on the animal's left were traumatized and examined 2 days later. An effort was made to keep the prothrombin level stable during the experimental period by feeding small maintenance doses of dicumarol.

A protocol of a typical animal experiment follows.

Protocol. Dog No. 8. Weight 12 kilograms. November 24, 1947. Prothrombin time 9.5 seconds (60 per cent). Coagulation time, 5 minutes. Radial, long and short saphenous veins on right traumatized.

November 26 Prothrombin time 9 seconds (80 per cent) Coagulation time 9 minutes Investigation of previously traumatized veins revealed thrombosis of the radial and short saphenous veins, patency of the long saphenous vein

November 28 Dicumarol 50 milligrams

November 29 Dicumarol 25 milligrams

November 30 Dicumarol 12.5 milligrams

December 1 Prothrombin time 23.5 seconds (3 per cent) Coagulation time 13 minutes Three veins on left traumatized Dicumarol 12.5 milligrams

December 2 Prothrombin time 12.5 seconds (19 per cent) Coagulation time 15 minutes

December 3 Prothrombin time 18 seconds (4.5 per cent) Coagulation time 22 minutes Examination of traumatized veins on left showed thrombosis in all three No ecchymosis nor hematoma present Animal discarded

The experiment was completed on 36 dicumarolized dogs. These animals could be divided into four groups. Group I (10 animals) with veins traumatized when the prothrombin time was in the range of 9 to 15 seconds (57 per cent down to 6.5 per cent), Group II (10 animals) with the veins traumatized when the prothrombin time was between 16 and 28 seconds (from 6 per cent down to 3 per cent), Group III (10 animals) with a prothrombin time range of 28 to 39 seconds (3 per cent down to 2 per cent) and Group IV (6 animals), with prothrombin times above 40 seconds (percentage under 2 per cent). The significant data with regard to these four groups are shown in the corresponding tables (Tables I-IV). For purposes of brevity, the prothrombin values and the coagulation times are indicated for the 3 significant days of the experiment, namely the day of trauma to veins, the intervening day, and the day of examination of veins for thrombosis.

COMMENT

In Table I, it will be noted that in this group of animals, a minimal dicumarol effect was produced. Nevertheless, in 7 of the 10 animals, the prothrombin percentage was below 30 on the day the veins were traumatized. Sometimes the prothrombin level was higher on the following days, sometimes it was lower. The coagulation times were within normal limits. Seventy per cent of the veins were thrombosed, only slightly below the 78.8 per cent found in the controls.

TABLE V—SUMMARY OF RESULTS

Group No	Prothrombin time range seconds	Prothrombin percentage range per cent	Number of veins	Per cent thrombosis	Per cent animals with hematoma
Controls	7.5-9	100	123	78.8	0
I	9-15	6-7.5	30	70	0
II	16-28	3-6	30	70	30
III	28-39	2-3	30	13.3	100 (2 fatal)
IV	Over 40	<2	18	11.1	100 (1 fatal)

The animals in Group II were dicumarolized to a degree commonly thought to be well within the therapeutic range (prothrombin percentages between 3 and 6 per cent). All of the animals showed one or more coagulation times slightly above normal. Hematomas were present in 3 of the animals. Nevertheless, the incidence of thrombosis was still high (70 per cent).

In the third group of animals (Table III) we find that the desired therapeutic effect of dicumarol has been obtained, since thrombosis occurred in only 4 out of 30 veins (13.3 per cent). However, to produce this effect, it was necessary to depress the prothrombin to a level below 3 per cent of normal. The coagulation time was frequently 3 to 5 times the normal value. Hematomas were present in all of the animals, and 2 died of hemorrhage during the experiment. Similar results are seen in the fourth group (Table IV) in which there were extremely low prothrombin levels (under 2 per cent).

A tabular summary of the results which were obtained in the control group and in the four groups which were treated in Table V may be seen.

CONCLUSIONS

Under the conditions of this experiment, moderate degrees of dicumarol-induced hypoprothrombinemia did not significantly reduce the incidence of thrombosis. At prothrombin levels below 3 per cent, it was found that there was marked inhibition of thrombosis and also an important increase in hemorrhagic complications.

PAPILLOMA OF LACTEAL DUCT

AMBROSE C. ESTES, M.D., and CHARLES PHILLIPS, M.D., Temple, Texas

THE purpose of this paper is to present study and follow-up data on 87 cases of intraductal or intracystic papilloma seen at Scott and White Hospital during the period 1921 to 1946, inclusive. Follow-up reports by questionnaire method have been obtained for 77 (88.5 per cent) of these cases. Of those patients seen prior to 1943, representing a 5 year survival group, 84.0 per cent have responded to our inquiry.

The condition of papilloma of lacteal duct refers to a tumor, rarely more than 2 to 3 centimeters in diameter and often microscopic in size, located most often within the central zone of the breast. It is essentially a complex papillary mass projecting into the distended lumen of the duct. The papillary mass is made up of branching, quite vascular stromal bands coated by normal duct epithelium and usually attached at only one point to the wall of the duct. Often there is found an associated widespread hyperplasia of ductal epithelium.

In the present series, study of the case histories, in each case, with the recorded pre-operative examination and opinion of the surgeon has given a unique opportunity to realize a practical point not emphasized hitherto in the literature, that is, that the papilloma is very often not the tumor which is felt at time of examination. As a rule, if a tumor is palpated, upon removal it is found to be an area of cystic mastitis, whereas, the intraductal papilloma or papillomas are often microscopic in size and are discovered only on careful study of the surgical specimen. Five exceptions to this rule were noted in this series. In these exceptional cases the papilloma was 1 to 2 centimeters in size, but a blood-filled cystic space had formed around it, causing the entire mass to be clinically palpable and surgically accessible.

Since bleeding at the nipple gives a clue to the probability of finding the chief disease

process in one or more ducts, we have found that a modification of the usual methods of examination in the laboratory will give a much higher rate of positive findings. Instead of simply searching for the tumor by multiple cross sections of the breast, the examination follows the pattern of anatomical distribution of lacteal ducts in radiating fashion from the nipple. The breast is placed skin surface down and after the nipple is located as the center, many cuts down to skin level are made in the breast from the nipple to the periphery so that the entire duct system is exposed. Usually the involved duct or ducts will be prominent because of brown or bloody fluid present and quick but careful dissection will usually show the tumor in the duct. Quick frozen section can be made from the area with diagnosis resting upon a sound foundation of fact. The whole process takes only a few minutes longer than the older cross section method, is based upon anatomical distribution of the lacteal ducts, yields a much higher percentage of positive findings, and demonstrates the widespread distribution of disease. In our experience lacteal papilloma occurs chiefly in the area identified by the brown or bloody fluid along the path of involved ducts although other areas including the nipple itself must be carefully searched. The pathologist is always faced with the problem of how much papillary hyperplasia constitutes a papilloma and he must decide that for each case, for, in breasts of the type under consideration, papillary hyperplasia is very common. In most cases the differential diagnosis between the benign and malignant form of this is quite difficult. In line with the current accent on cytological study of fluids and smears we believe that detailed study of cells involved will help greatly. The work of Jackson and his associates is of great value in this field but we prefer excision biopsy. It is unusual to fail to find the pathological process if the radial dissection method is carried out.

From the Departments of Surgery and Surgical Pathology of the Scott and White Clinic, Temple, Texas

Diagnosis of this lesion rests squarely on microscopic evidence, however, certain clinical procedures are of definite aid. In addition to a careful history and inspection and palpation of the suspected area it is agreed that an attempt to express secretion from the nipple should be made. If this is successful, a slide should be prepared and submitted to the pathologist for examination as to presence of red blood cells and, rarely, of tumor cells. Transillumination of the lesion is generally considered a help in diagnosis for the blood-filled space which may surround the papilloma is opaque to light. Hicken recommended use of skiodan viscous as a contrast medium injected into the lacteal ducts to elicit the filling defect produced by these tumors. In regard to management of this lesion, it is emphasized by most observers that in the presence of cardinal symptoms of intraductal papilloma, either tumor or bleeding from the nipple, or both, surgery is required. Especially is this true since in approximately 50 per cent of cases of bleeding nipple a malignant lesion is revealed on exploration. The difference of opinion rests with the extent of the indicated surgery when an entirely benign lesion is encountered.

In separate reports based on series of 52 and 55 cases, respectively, Wakeley and Campbell urge simply local or wedge excision unless the lesion is multiple at time of surgery. Gray and Wood of the Mayo Clinic contended that bloody discharge is a serious sign and preferably merits simple mastectomy. However, no follow-up data are included in their study. Hicken emphasizes the work of Cheate and Cutler, Adair, and others who have made serial sections of removed mammary glands. They had found papillomas to be multiple in a high percentage of cases, encountering as many as 150 separate and distinct papillomas scattered in one breast. Papillomas have been stated to be multiple in 15 to 37 per cent in 3 previously reported series. Here, 21.7 per cent were multiple, and in 2 (2.3 per cent) instances were bilateral. Also, Stowers, Hicken, and others have pointed out the coexistence of papilloma with papillary carcinoma, and the resultant necessity for assurance that all the discrete entities in the particular breast be eradicated. Our series contains 3 cases of this

latter category which will be mentioned in the follow-up study.

Briefly, arguments for a conservative local excision resolve themselves into (1) cosmetic and psychologic, (2) absence of demonstrated pathologic changes in the remaining breast tissue, and (3) lack of proof that the patient's risk is thus increased. Main arguments for simple mastectomy are (1) the 15 per cent "recurrence" rate following local excision, (2) the possibility of overlooked multiple papillomas with later malignant changes, and (3) overlooked papillary carcinoma in another portion of the same breast.

CLINICAL FEATURES

The clinical features noted in lacteal papilloma are summarized in the following paragraphs. These data conform closely to those in series reported by Geschickter and Grant and Wood.

Of the total of 87 histologically proved cases of intraductal papilloma, 81 patients (93 per cent) were married and 6 single at the time of admission. A family history of cancer was mentioned by 21 patients. One or more pregnancies were noted for 57 patients. The average age was 44 years, ranging between 26 and 67 years.

Twenty patients had records of previous breast surgery, more often on the opposite breast, and this was of varied type, including incision for "abscess," excision of lipomas or areas of cystic mastitis. The left breast was involved in 40 cases, the right in 36, and there was involvement of both breasts in 11 cases. The chief complaint upon admission concerned the breast in 81 cases. Since most patients had been referred, it is believed that this latter figure is probably abnormally high as compared to that which might be expected in routine office practice. Since these tumors are small and painless, in the absence of discharge examination of the nipple area as a matter of routine becomes of importance for diagnosis.

Duration of symptoms was variable, averaging 10 months but ranging from 1 month in 14 cases to 20 years in 1 case, and long time discharge, sometimes bloody in type, was not uncommon. Although all observers agree that sanguineous nipple discharge merits ex-

TABLE I

Total	39	47

Note Another patient, the 87th of the series had radical mastectomy performed for extensive associated cystic mastitis of borderline histologic malignancy. She is in good health 12 years following surgery.

ploration, it bears re-emphasis that the finding is purely a symptom and, in roughly 50 per cent of cases, a benign lesion will be encountered.

All patients in this series had findings of either nipple discharge, tumor, or both (Table I). As pointed out earlier, the tumor palpated was usually not the intraductal papilloma but more often was an area of cystic disease. It is apparent upon dividing the cases into two groups depending on type of surgery performed that the tendency here at Scott and White Hospital during this period has been for the operator to remove the local tumor and, when the frozen section is reported benign, to close the wound. Conversely, when bloody discharge is a symptom, a simple mastectomy is more likely to be undertaken. This latter judgment is supported by the work of both Lepper and associates and Adair who independently have performed multiple serial sections of these specimens and remark the difficulty of finding the microscopic multiple tumors even by this careful technique.

Ten cases bearing the clinical diagnosis of probable intraductal papilloma were also studied. In 9 cases the chief complaint was of nipple discharge and in the tenth, a small tumor within the nipple. Eight of these patients were followed. Four refused surgery and report good health after 2, $3\frac{1}{2}$, 2, and 4 years respectively. One of these patients mentions persistence of brownish nipple discharge. Three patients accepted simple mastectomy, but no papilloma was found in the excised tissue. These patients reported no additional trouble in 4, $4\frac{1}{2}$, and 5 years respectively. One patient accepted surgery

elsewhere, a papillary carcinoma was found, and a radical mastectomy performed. She reports herself in good health 7 years after surgery.

FOLLOW-UP STUDY

Table II summarizes our experience here as obtained by follow-up questionnaires, letters from referring doctors, and data from the Bureau of Vital Statistics, Department of Health, State of Texas.

In the 42 cases of unilateral or bilateral simple mastectomy for proved histologic intraductal papilloma which were followed, the patients were found to have absolutely no further trouble, to have remained in good health generally, and to have had no subsequent operations. This is in accord with Geschickter's report on 39 of 46 similar cases. No instances of supervening cancer were noted.

It might be mentioned that the 3 cases in the files here of grade 1 papillary carcinoma in association with intraductal papilloma with simple mastectomy performed were followed also. One patient is a 7 year survival in apparent good health, another is a 14 year survival for whom recently a radical procedure on the same breast was performed elsewhere for large local recurrences without evidence of distant metastases. The third patient has been followed less than 2 years and her health is reported excellent. Three additional patients had radical mastectomy performed for coexisting carcinoma grades 2 or 3. Follow-up on 2 of these patients revealed 1 survival for 2 years, and 1 death after 3 years ascribed to cancer of the breast with metastasis. Whether the foregoing 6 cases represent instances of malignant transformation of an intraductal papilloma remains conjecture.

The 34 cases followed sequential to local or wedge excision of the lesion tell a slightly different story. Further trouble is indicated by 4 of these patients. One reports another small lump near her incision. Another patient has had subsequent bilateral simple mastectomy here for breast tumors. Pathologic report was cystic mastitis in one breast and papilloma in the other. A third patient has had simple mastectomy performed upon the same breast. The fourth patient has had 6 operations on the breasts in the course of 15 years, with papillomas found in 2 instances. Although this represents only 11.7 per cent who have reported further trouble, it compares with Geschickter's reported data in which 8 of 110 (7.3 per cent) patients for whom local excision was performed were operated upon later for "recurrent" papilloma. This is especially interesting, for Geschickter advocates merely local excision for single benign papilloma. It is our opinion from these data rather than simple mastectomy is the procedure of choice for attempted cure of this condition as papillomas may be multiple, may be present in more than one duct, and, contrary to some authorities, may become malignant. There is evidence in our series that additional operations have been necessitated. There is no evidence from this study that local excision of the lesion has resulted in development of a later cancer, but the possibility of malignant change in overlooked multiple papillomas is certainly conceivable. Again, in Geschickter's group, 3 of 54 such patients, followed for more than 5 years, had developed mammary cancer. Hart, who reported upon the only comparable series in the literature with follow-up study, found strikingly similar results. Of 66 patients followed with 95 benign intraductal papillomas (69.5 per cent), none developed cancer but 9 patients were reoperated upon for another papilloma and 6 were reoperated upon for a bloody nipple discharge. Clinically, when there is a

small discrete, mobile tumor at or near the areola, pressure upon which produces secretion at the nipple, a papilloma is probably present and perhaps a local excision is contemplated. However, from our study we believe that even in this type of case the patient should be told that such a tumor 1 time out of 5 (15 to 30 per cent) is multiple and reoperation may be necessary unless simple mastectomy is done at the outset.

SUMMARY

A follow-up study of 77 patients, or 88 per cent of 87 cases of microscopically proven intraductal papilloma seen at Scott and White Hospital in the period 1921 through 1946, have been presented. Clinical features and principles of surgical management have been discussed. Subsequent trouble in the same breast was reported in 11.7 per cent of 34 cases in which segmental excision of the lesion was carried out. In the 42 cases followed in which simple mastectomy was performed no further trouble developed. No patients in this series are known to have developed cancer of the breast sequential to operation.

CARCINOMA OF THE THYROID GLAND

WARREN H COLE, M D, F A C S, DANELY P SLAUGHTER, M D, F A C S,
and JAMES D MAJARAKIS, M S, M D, Chicago, Illinois

THERE is great variation in the incidence and other characteristics of this disease, as indicated by the reports of different investigators from various parts of the country. This variation in incidence suggests that carcinoma of the thyroid gland is a geographical disease. In our report 4 years ago we noted an incidence of cancer equal to 17.1 per cent in nontoxic nodular goiter (Table I). This appeared to be an unusually high incidence of carcinoma in goiter, but since previous investigators had not broken down their series into nontoxic and toxic nodular goiter, but usually gave one figure for all types of thyroid glands encountered in the surgical pathology laboratory, there was relatively little previous data with which to compare ours. Thinking that our series, which was relatively small, might have reflected a high incidence through coincidence, we have continued the study and analyzed the cases observed in our clinic during the 3½ year period since the original publication. Of the 93 patients operated upon for nontoxic nodular goiter, between 1944 and 1948, 17.2 per cent had carcinoma. The incidence in the two periods has remained remarkably identical. Altogether in the 11½ year period since 1936, up to January 1, 1948, 17.15 per cent of the 285 nontoxic nodular goiters removed in the operating room were carcinoma. Of still more significance was the fact that of the solitary nodules which comprised about one-half of the group 24.4 per cent were carcinoma in contrast to only 9.8 per cent for the multinodular types of nontoxic nodular goiter (Table II). The incidence of carcinoma in both types of nodular goiter (toxic and nontoxic) rose from 7.2 per cent in the first series to 11.3 per cent in the latter series (1944 to 1948), but this increase should be ignored because it is ex-

plained by the relatively smaller number of toxic nodular goiters observed in the latter period.

The data in Table II reveal only 1 case of carcinoma in 517 cases of toxic diffuse goiter operated upon in the 11½ year period. This constitutes an incidence of 0.2 per cent, agreeing with the experience of others. For example, Ward encountered only 1 carcinoma in 1900 patients with toxic diffuse goiter. In 378 specimens of toxic nodular goiter removed at operation in the 11½ year period, we encountered carcinoma of the thyroid in only 4 patients. It is obvious, therefore, that presentation of figures on incidence of carcinoma on all thyroid specimens combined, as removed from the operating-room, are entirely misleading, and do not give the correct emphasis on incidence, particularly as related to types of goiter. In other words, if a toxic diffuse goiter is present, one can almost dismiss completely the possibility of carcinoma, particularly if the toxicity is of more than a mild type.

Since our initial report showing a breakdown of incidence of carcinoma in various types of goiter, other investigators have computed the incidence in each group, e.g. Crile reported a 10.9 per cent incidence of carcinoma in 274 specimens of nontoxic nodular goiter, which is considerably less than our figures. However, the incidence of carcinoma in the solitary type of nontoxic nodular goiter was almost identical to that in our series, being 24.5 per cent and 24.4 per cent respectively.

Crile has very appropriately called attention to the fact that patients who are hospitalized and operated upon for nontoxic nodular goiter have in reality been screened, particularly by the patient and the internist, and has emphasized that the incidence as reported from hospitals is not a true incidence in all patients with nontoxic nodular goiter. We agree with him on this point, but its importance appears to be minimized to a certain extent by the comparison of our statistics in

From Department of Surgery, University of Illinois College of Medicine and Illinois Research and Educational Hospitals.

Presented in the Symposium on Malignant Lesions of the Thyroid Gland before the Clinical Congress of the American College of Surgeons, Los Angeles, October 18 to 22, 1948.

TABLE I—INCIDENCE OF CARCINOMA IN NODULAR GOITER (INCLUDING TOXIC, NONTOXIC AND CARCINOMA) ILLINOIS RESEARCH HOSPITAL 1936-1948

Type of goiter	1936-1944		1944-1948		1936-1948	
	No cases	Per cent carcinoma	No cases	Per cent carcinoma	No cases	Per cent carcinoma
Toxic nodular	330	1.2	48	0	378	1.0
Solitary	71	0.0	17	0	88	0.0

Solitary	92	24.0	51	25.5	143	24.4
Multinodular	100	11.0	42	7.1	142	9.8
Total	522	7.2	141	11.3	663	8.0

1936 to 1944 to those of 1944 to 1948. Following 1944, when we noted such a high incidence of carcinoma in nontoxic nodular goiter (particularly of the solitary type), we recommended thyroidectomy in every patient with such a lesion, with practically no exceptions. Patients accepted our advice and had a thyroidectomy performed. Even though we operated upon all these patients with solitary nodules, our incidence of carcinoma in nontoxic nodular goiter remained the same.

The supposition that goiter, including carcinoma of the thyroid gland, is a geographic disease is supported by figures from different parts of the country. For example, Rogers and associates noted that in 544,918 patients admitted to the Boston City Hospital, the Massachusetts General Hospital, and the Johns Hopkins Hospital over a period of several years, only 0.59 per cent were admitted for goiter. In 68,573 admissions to the Illinois Research Hospital during an 11½ year period, there was an incidence of 1.7 per cent goiter, which is roughly three times that of the Atlantic seaboard. After all, there is nothing new in these data since it is well known that goiter is more common in goiter belts, and figures in nongoiter belts cannot be compared to those in goiter belts. It is even more fallacious to attempt to determine the incidence of carcinoma in goiter from autopsy statistics, as has been suggested by Vanderlaan. He reports that in 18,668 autopsies performed at the Boston City Hospital over a period of 50

TABLE II—INCIDENCE OF CARCINOMA IN VARIOUS TYPES OF GOITER (INCLUDING CARCINOMA) ILLINOIS RESEARCH HOSPITAL 1936-1948

Type of goiter	No cases goiter	No cases carcinoma	Per cent carcinoma
Toxic diffuse	517	1	0.2
Toxic nodular	378	4	1.0
Nontoxic nodular	285	49	17.15
Solitary	143	35	24.4
Multinodular	142	14	9.8
Total	1180	54	4.6

years, there were only 5 cases of carcinoma, and implies that this might be interpreted as data on incidence. We are convinced that autopsy figures are worthless in attempting to determine incidence of carcinoma and quote figures from the Illinois Research Hospital to support this statement. For example, during the second period (1944 to 1948) of our study, there were 675 autopsies at Illinois Research Hospital. Only 2 were for carcinoma of the thyroid. During this same interval 16 patients with carcinoma were encountered in the operating room and their condition diagnosed as such by the Department of Pathology. The astounding feature is that of the 16 patients followed in this series, we know that 11 are already dead. However, autopsies were not performed upon any of these 11 patients in our hospital, the 2 autopsies which were made during this 1944 to 1948 period belonged to the 1936 to 1944 series. It must be realized that patients with certain diseases are not referred to the hospital to die. Since these patients were able to receive all possible care as ambulatory patients, we did not refer them to the hospital when the disease became terminal, largely because the insufficient number of hospital beds available are reserved for patients for whom we hope to obtain better results than those indicated in terminal carcinoma of the thyroid. Any suggestion that our pathologists are more liberal with the diagnosis of hyperplastic lesions than others can certainly be refuted emphatically by the fact that 11 of the 16 patients with carcinoma in this latter series (1944 to 1948) are already dead, and 2 of the 5 known to be living have metastases. We know that all those who died had metas-

TABLE III — CHARACTERISTICS OF VARIOUS TYPES OF NODULAR GOITER

Illinois Research Hospital
1936-1948

Type of lesion	Total No	Average	Sex per cent F	Race per cent Col	Duration mass years	No solitary
Toxic nodular goiter (benign)	378	43.5	88.9	9.4	9.9	84 (22.4%)
Nontoxic nodular goiter (benign)	285	42.4	90.1	18.0	10.2	108 (37.9%)
Carcinoma of thyroid	54	48.0	67.0	13.0	6.1	35 (64.9%)
Total	717					

tases Although we cannot prove that the cause of death in every instance was carcinoma, yet the fact that all had demonstrable metastases should dispel any doubt regarding accuracy of the diagnosis

Carcinoma of the thyroid is much more apt to develop in men with nodular nontoxic goiter than in women, for example, of 663 patients with nodular nontoxic and nodular toxic goiter as observed at the Illinois Research Hospital from 1936 to 1948, only 10 per cent were males contrasted to an incidence of 33.3 per cent males in 54 cases of carcinoma encountered during that same period (Table III). This indicates that the probability of development of carcinoma is about three times as great in men as in women, a point which Ward has emphasized for years. This figure is quite similar to that reported by other investigators in this field. Ward has noted further that in his entire series covering 20 years, the incidence of carcinoma in men with nodular goiter is 12 per cent, but in recent years this percentage has risen to 16.6 per cent. Our incidence of carcinoma in men with nodular goiter (toxic and nontoxic) is 17.5 per cent and likewise has shown an increase in the past few years. In our series of 54 patients with carcinoma of the thyroid the average age was 48 years, which is identical to the average as reported by Lahey, Hare, and Warren (13, 14). In fact, all investigators have reported that the average age of a patient with carcinoma of the thyroid is much lower than the average age of patients with other types of carcinoma because it is so common in young people. For example, in 62 children 14 years of age or under with nodular goiter, Kennedy

TABLE IV — INCIDENCE OF CARCINOMA IN NODULAR GOITER AS OBTAINED FROM NUMEROUS REPORTS IN THE LITERATURE

Author	No patients with nodular goiter (toxic and nontoxic)	Per cent carcinoma in nodular goiter (toxic and nontoxic)	No patients with nodular nontoxic goiter	Per cent carcinoma in nodular nontoxic goiter	Per cent carcinoma in solitary nontoxic nodular goiter
Brenner and McKnight Charlotte N C 1940	2324	4			
Horn and associates Philadelphia Pa 1947	1135	6.3	637	9.8	
Crile Cleveland Ohio 1948	537	5.6	274	10.9	24.5
Ward San Francisco 1947	3539	4.8			15.6
Cole and associates Chicago 1948	663	8.0	285	17.1	24.4

encountered carcinoma in 12 cases, representing an incidence of 19.3 per cent. This series alone emphasizes the seriousness of goiter in young people. Ward noted an incidence even higher, namely 40 per cent in 10 children under 15 years of age with nodular goiter. The percentage of colored people in our series of carcinoma of the thyroid was 13 per cent, which is identical to the percentage of colored patients in our group of nodular goiter, toxic and nontoxic.

The average duration of the mass in our patients with carcinoma was 6.1 years (Table III). In our patients with toxic nodular (benign) goiter the average duration of the mass was 9.9 years, as compared to 10.2 years for nontoxic nodular (benign) goiter. The 6.1 year history of a mass in the neck in patients with carcinoma appears to be fairly good evidence that carcinoma develops in pre-existing nodules or adenomas. In fact, almost all investigators in this field agree that most carcinomas of the thyroid have onset in benign nodules or adenomas, frequently of the fetal adenoma type.

RELATIONSHIP TO HYPERTHYROIDISM

Carcinoma is extremely uncommon in toxic diffuse goiter. For example, in 517 cases of toxic diffuse goiter operated upon during the

TABLE V — PATHOLOGIC TYPES IN 54 CASES OF THYROID CARCINOMA OBSERVED IN ILLINOIS RESEARCH HOSPITAL 1936-1948

Type	Number	Per cent
1 Papillary adenocarcinoma	15	27.7
2 Alveolar adenocarcinoma	11	20.4
3 Hürthle cell adenocarcinoma	7	12.9
4 Small cell diffuse carcinoma (carcinoma simplex)	4	7.5

Total	54	100.0

*If Shields Warren's classification were used many of these would be classed as malignant adenoma.

past 11½ years, we encountered only 1 carcinoma. Ward encountered 1 case of carcinoma in 1900 cases of toxic diffuse goiter. Carcinoma is more common in toxic nodular goiter, but in general is so uncommon in toxic goiter that presentation of a figure on incidence of carcinoma *for all types of goiter are in reality misleading*, since the incidence is so many times more common in nontoxic nodular goiter. We encountered 4 patients with carcinoma in 378 patients having thyroidectomy for toxic nodular goiter. All together, hyperthyroidism was associated with carcinoma of the thyroid in 9 per cent of our series, but in general was quite mild in type.

There is considerable variation in figures presented by other workers. The highest incidence is that reported by Pemberton and Lovelace (17, 18), namely 33.5 per cent. However, this figure is far above most of the other figures in the literature. Horn and associates noted that thyrotoxicosis was present in 9 per cent of 71 cases of carcinoma studied by them. McSwain and Diveley encountered definite hyperthyroidism in 10 per cent of 22 cases of carcinoma and doubtful hyperthyroidism in an additional 10 per cent.

There is controversy as to the origin of the thyrotoxicosis when it occurs with carcinoma. However, after a study of 396 patients with carcinoma of the thyroid, Friedell arrived at the conclusion that the carcinomatous area itself does not have the function of hyperthyroidism. We agree with this conclusion, but are aware of a few instances in which the metas-

tases appeared to have produced hyperthyroidism.

PATHOLOGY

It is not our intention in this paper to discuss the details of pathology of carcinoma. As previously stated, most authorities working on this subject are of the opinion that carcinoma of the thyroid has its origin in benign nodules or adenomas in a large percentage of cases. A classification of Shields Warren includes malignant adenomas as one of the types observed, although some pathologists prefer to place these tumors in other categories. Table V reveals the types of tumors encountered in our series. Twenty-seven per cent are shown as lesions which some pathologists might classify as malignant adenomas. It is important that this group, which is classified by some authors as malignant adenomas, is slow to metastasize as are also the papillary carcinomas. In our series 27.7 per cent were papillary carcinomas. In other series the incidence of this type of tumor is higher. In 517 cases of carcinoma of the thyroid Pemberton (17, 18) reports 30 per cent as being papillary carcinoma, 38 per cent as carcinoma in adenoma, and 30.4 per cent as diffuse adenocarcinoma.

There is considerable difference of opinion as to the incidence of malignancy in lateral aberrant thyroids. After analyzing 34 cases of lateral aberrant thyroid nodules, Lahey (12) reports that 35 per cent were carcinoma. Crile noted that "in nearly half the cases of lateral aberrant thyroid disease, the lobe of the thyroid on the affected side contained a tumor histologically identical with the lateral cervical nodes." King and Pemberton (11) considered all such nodules as metastases from the homologous lobe of the thyroid. After a study of 112 cases, Black has concluded that lateral aberrant thyroids are metastases from primary lesions in the thyroid and are practically always of the papillary adenocarcinoma type.

DIAGNOSIS

Unfortunately, there are no early symptoms of carcinoma of the thyroid except rapid increase in the growth of the nodule in the neck. The remainder of the symptoms as noted below are in reality late symptoms. The

first complaint noted after increase in the size of the mass in the neck is apt to be a feeling of pressure in the neck, particularly when the patient moves his head in certain directions. Hoarseness is fairly common and is indicative of pressure on one of the laryngeal nerves or invasion of the larynx or trachea itself. Persistent cough with excessive mucus is not uncommon. Difficulty in breathing and swallowing are later symptoms and usually indicate invasive growth of the tumor compressing the trachea or larynx, or esophagus respectively. Along with difficulty in breathing, stridor is occasionally noted, particularly while the patient is asleep.

Soley and associates have called attention to the fact that pressure symptoms are by no means pathognomonic of cancer of the thyroid. For example, in 72 of 81 patients with nonmalignant nodular goiter, pressure symptoms of one type or another were present. This incidence is remarkably similar to the incidence of pressure symptoms in carcinoma of the thyroid, insofar as 12 of 15 patients with carcinoma had one or more types of pressure symptoms.

Examination of the mass is helpful but by no means will make a positive diagnosis, since the consistency of the different types of tumors varies. Obviously, any indurated tumor mass must be considered as potentially malignant, although thyroiditis is about as common and must be ruled out. Of more value than consistency of the tumor is the presence of metastatic nodules in the neck.

Considering the manifestations described, it is obvious that it will be very difficult to make a preoperative diagnosis in a high percentage of cases, as is borne out by actual experience. For example, McSwain and Diveley report that in 27 per cent of their series of carcinoma of the thyroid, the diagnosis was not suspected preoperatively. In the series reported by Pemberton (17, 18), carcinoma was unsuspected in 60 per cent. In our report (2) 4 years ago, our figure on preoperative diagnosis actually was less than reported above. However, since that time we have made much greater effort to differentiate benign from malignant lesions of the thyroid, but have been able to make a correct preoperative diagnosis

in no more than 75 per cent of cases, even then we had to have the assistance of preoperative biopsy to attain this figure.

However, Crile reports an accuracy of 90 per cent preoperative diagnosis of carcinoma of the thyroid, although he admits that it may not be possible to maintain a percentage accuracy as high as this.

TREATMENT

Since it appears that carcinoma of the thyroid frequently develops within benign nodules, the removal of nontoxic nodular goiter becomes an important method of therapy in the treatment of carcinoma of the thyroid although it is obviously prophylactic. Practically all the authorities reporting on the incidence of carcinoma have arrived at the conclusion that all nodular goiter of the solitary type should be removed. The authors agree with this conclusion. Hinton and Lord made a study of the incidence of carcinoma in 184 patients with clinically benign nodular goiter (toxic and nontoxic) finding that 7.6 per cent were carcinoma. In 75 patients with clinically benign lesions of the breast, carcinoma was encountered in 6.7 per cent of the group. They, therefore, conclude that there is actually more reason for removing an apparently benign nodule in the thyroid than an apparently benign nodule in the breast. They emphasize that practically all physicians advise removal of all nodules in the breast even though they appear benign. After this study they conclude that "all nontoxic nodular goiter should be removed because of the high incidence of unsuspected cancer, a rate which exceeds that of cancer of the breast in the clinically benign appearing group." Practically all surgeons now agree that even though a nontoxic nodule in the thyroid appears quite definitely to be benign, it *must not be removed by simple enucleation*, but that a subtotal thyroidectomy of the affected lobe should be done, because early carcinoma is so frequently found in the nodule.

Opinions differ somewhat as to the actual type of treatment, although it is agreed that surgery and irradiation therapy (including radon seeds) are extremely valuable. The authors favor radical dissection of the neck in all cases of carcinoma of the thyroid except

TABII VI—FIVE YEAR SURVIVAL RATES IN CARCINOMA OF THE THYROID AS REPORTED BY NUMEROUS OBSERVERS IN THE LITERATURE

Author	No. patients followed 5 years	Per cent 5 year survival
Pemberton Rochester Minn 1918	421	61
Horn and associates Philadelphia Pa 1918	42	55
Cole and associates Chicago Ill 1918	36	39
Portmann Cleveland Ohio 1910	119	15.5
DeQuervain Switzerland 1915	105	17.5
Dargent Lyon France 1911	115	0.6
Watson and Pool New York 1910	167	7.5

those in which a small carcinoma is found within the thyroid tissue in the surgical pathology room. By radical dissection of the neck we mean excision of the sternomastoid muscle, internal and external jugular, the ribbon muscles, and all areolar and lymphatic tissue on the affected side. Details of the operation may be found in the publications of Lahey (13, 14), and Watson and Pool. Some surgeons (Crile) are not convinced that radical resection adds a great deal to the ultimate results. Black is of the opinion that radical dissection is not necessary in the malignant lateral aberrant thyroid.

Radium and x-ray treatment are quite effective in certain types of lesions particularly the papillary adenocarcinoma. Either or both of these types of therapy should be utilized in every patient with carcinoma of the thyroid revealing metastases, regardless as to whether or not radical resection has been performed.

When radioactive iodine was introduced as a method of treating carcinoma of the thyroid, great hope was held out for good results, since it was known that the thyroid gland picked up iodine from the blood stream. However, reports from numerous workers have not been very encouraging. For example, Marinelli re-

ports that in 19 cases of carcinoma of the thyroid only 11 took up radioactive iodine. Rawson reports that in 12 patients with carcinoma only 5 took up iodine, whereas all benign tumors of the thyroid did. In 8 cases the metastatic nodules took up radioactive iodine but not in quantities as great as did normal tissue. They concluded that this function which was present in normal thyroid to a great extent, was actually lost when carcinoma developed. Ward reports that in 10 patients of the California series, treated with radioactive iodine, there was no measurable pick-up of radioactive iodine in 7. From the reports mentioned, it is rather obvious that radioactive iodine will contribute very little to the treatment of carcinoma of the thyroid except in the occasional case.

RESULTS

The operative mortality following thyroidectomy for carcinoma of the thyroid will be somewhat higher than thyroidectomy for benign lesions of the thyroid, but will vary depending largely upon the percentage of radical neck dissections. Pemberton reports an operative mortality rate of 1.8 per cent. Portmann noted a mortality rate of 8.5 per cent, although many of these patients are drawn from records many years ago. We had 1 operative death in 36 patients upon whom we did a thyroidectomy or thyroidectomy with radical neck dissection, constituting a mortality rate of 2.7 per cent. Seven of these 36 patients had radical neck dissections without operative fatality.

In general it is agreed that the best results will be obtained in papillary carcinoma, Hürthle cell carcinoma, and malignant adenoma, perhaps in the order named. After studying their series of cases, McSwain and Diveley concluded that the duration of the mass in the neck had no bearing on prognosis. Dailey emphasizes that the presence of distant metastases should not be considered too seriously in issuing a pessimistic prognosis. For example, he noted that 10 of 90 patients studied by him had remote metastases for 3 to 17 years. All investigators studying the problem of carcinoma of the thyroid have known of patients with metastases in bone or other organs.

which have been present for years without much evidence of spread

There is an enormous variation in the 5 year survival rates reported by various authors. For example, in 421 patients followed for 5 years at the Mayo Clinic, Pemberton (17, 18) reports 61 per cent 5 year survivals (Table VI). On the contrary, Watson and Pool reported only 7.8 per cent 5 year survivals in 167 patients, and Dargent reported only 9.6 per cent in 135 patients. De Quervain reported a slightly higher rate of 17.5 per cent in 108 cases followed 5 years or more. Our series of patients, observed 5 years or longer, is quite small. Of 36 patients having complete follow-up, 38 per cent survived 5 years or longer. The survival rate for our late series will probably be less than this, since in 11 of the 16 cases followed (3 months to 5 years) death has already occurred.

It is difficult to explain the wide variation in 5 year survival rates as reported above. It is assumed that certain observers may be more lenient in allowing doubtful cases to be classified as carcinoma, however, the authors are not at all convinced that this is the sole explanation. We are convinced that coincidence and geographic location are probably of greater importance in this variation of figures, largely because the incidence of papillary carcinoma (particularly of the lateral aberrant type) and other relatively slow growing tumors will show great variation geographically. It is quite obvious that in the 16 patients, followed closely during the past 4 years, we have been dealing with a very vicious type of tumor, since 11 are already dead.

As in other types of malignant tumors, the relative curability is dependent upon how extensively invasion has taken place when treatment is instituted. For example, Ward found that in patients whose disease was diagnosed before operation, the 5 year survival rate was 20 per cent, whereas in those patients whose condition was diagnosed only after examination of the specimen in the surgical pathology room it was 80 per cent.

SUMMARY

During the past 11½ years we have encountered 54 patients with carcinoma of the

thyroid in 663 patients having thyroidectomy for nodular goiter, constituting an incidence of 8 per cent. The incidence of carcinoma in toxic nodular goiter was only 1 per cent, contrasted to 17.15 per cent in nontoxic nodular goiter.

In a study made by us (2) 4 years ago the incidence of cancer in nontoxic nodular goiter was 17.1 per cent. Since this appeared unusually high, we have analyzed the data during the past 4 years and found it to be almost identical, namely 17.2 per cent. Of the solitary nodules, which comprised half of the group of nontoxic nodular goiters, 24 per cent were cancer, in contrast to only 9.8 per cent for the multinodular type of nontoxic nodular goiter. Statistics on cancer including all types of goiter are entirely misleading because the incidence is so low in toxic goiter. The incidence of cancer in our series of 517 patients with toxic diffuse goiter was only 0.2 per cent.

Goiter, including cancer of the thyroid, is a geographical disease. The ratio of goiter to all admissions in our hospital is three times greater than in hospitals along the Atlantic seaboard. It is worse than worthless (i.e. entirely misleading) to attempt to determine the incidence of cancer in goiter from autopsy statistics. Our study of patients encountered in our clinic during the past 4 years reveals the fact that 11 of the 16 patients with carcinoma of the thyroid are already dead from their cancer, yet none of these 16 was autopsied in our hospital. One or two died in other hospitals, the rest died at home.

The danger of cancer in goiter is about three times greater in men than in women. The average age of patients with carcinoma of the thyroid is much lower than the average age of patients with other types of cancer because it is so common in young people. Most carcinomas have onset in benign nodules or adenomas as indicated by the fact that the average duration of the mass in our combined series was 6.1 years.

The preoperative diagnosis in early cases is extremely difficult. During the past 4 years when we have been extremely careful in the diagnostic study of our cases we have been able to make a correct diagnosis in no more than 75 per cent of patients with carcinoma,

even then we had the advantage of a biopsy in a few cases. Rapid increase in the growth of the nodule, a feeling of pressure, hoarseness, persistent cough, difficulty in breathing, and an indurated tumor mass are of help in making this diagnosis. The first symptom is the earliest, the remainder are usually indications of metastases or invasion outside the gland.

When a cancer of the thyroid has invaded the capsule or metastasized to cervical lymph nodes, it should be treated by radical neck dissection and radiation therapy, sometimes including radon seeds. Reports of other investigators indicate that radioactive iodine will be of only slight help in controlling this disease.

The 5 year survival rate as reported by numerous authors varies greatly (from 61 to 78 per cent in 7 reports reviewed by us) due in part to the different criteria used in making the microscopic diagnosis, and in part to geographical locations. In our series it was 38 per cent, but in our late cases, the figure will probably be lower since 11 of 16 patients observed during the past 4 years are already dead.

The incidence of cancer in the solitary type of nontoxic nodular goiter is so high in our locality that we advise removal of all solitary nodules, but perform subtotal hemithyroidectomy rather than enucleation because early cancer will be found unexpectedly in a surprisingly large number. During the past 4 years we have advised and removed practically all solitary nodules encountered in patients in our clinic, but in spite of this the ratio or per cent of cancer has not decreased over

that encountered in our initial series reported 4 years ago.

PREOPERATIVE EVALUATION OF LIVER FUNCTION IN PATIENTS WITH CIRRHOSIS OF THE LIVER

ARTHUR H. BLAKEMORE, M.D., New York, New York

THE great strides that have been made in the protective and supportive measures for the treatment of the impaired liver have enabled the surgeon of today in most instances to undertake and carry out successfully long and tedious operative procedures. These advances bring into focus the importance of accurate preoperative evaluation of the extent of liver damage and its functional capacity in a given case.

An analysis of 44 cases of disease of the liver (42 of cirrhosis) in which the operation of portacaval anastomosis was performed affords some opportunity of correlating the preoperative evaluation of the status of the liver with its postoperative behavior.

It became apparent early in the series that no single liver test employed by us afforded consistently adequate information upon which to predict the behavior of the liver postoperatively in a given case. On the other hand, there was the occasional patient whose postoperative progress was better than could be anticipated on the basis of several preoperative liver tests.

This is best illustrated by citing the case of an 18 year old girl who gave a 5 year history of progressive, unremitting, painless jaundice. Hepatosplenomegaly was known to have existed for 2 years prior to her admission to the Presbyterian Hospital. A dietary medical regimen for cirrhosis of the liver was without effect in this case. Over the years there had been a progressive severity of the jaundice with decline in the serum albumin. A liver chemistry survey 6 months prior to admission revealed a 2+ cephalin flocculation reaction, serum albumin was 3.2 per cent, globulin 4.4 per cent, and cholesterol esters less than 50 per cent of the total. On admission, the cephalin flocculation was 4+, thymol turbidity, 4+, serum albumin, 3 per cent, globulin,

2.9 per cent, serum phosphatase, 3.9 Bodansky units per cent, bromsulfalein retention 45 minutes after injection was 37 per cent, the galactose removal constant was 50 per cent of normal (21), the prothrombin time was 60 per cent of normal and the serum bilirubin 3.6 milligrams per cent.

The spleen was markedly enlarged. A venous hum could be heard below the xyphoid process. All concurred that this patient was a bad operative risk. Nevertheless she tolerated the operation of splenectomy and anastomosis of the splenic vein to the renal vein surprisingly well. Postoperatively, as evidence of further depressed liver function, she developed edema and ascites on the third day. There was anorexia and lassitude but the patient took a high protein diet courageously, and following a paracentesis on the sixth postoperative day there was no further recurrence of the ascites. By the seventh postoperative day the serum bilirubin had dropped 30 per cent below its preoperative level. At the end of 3 weeks the serum albumin had risen to 3.4 per cent.

At the time of discharge on the thirty-ninth postoperative day, the patient was free of jaundice for the first time in 5 years. The total serum proteins had risen to 8.3 per cent (albumin 4.8 per cent, globulin 3.5 per cent). The cholesterol esters had risen from a preoperative figure of less than 50 per cent to 66 per cent of the total cholesterol. There had been improvement in the bromsulfalein and galactose tolerance liver function tests. The thymol turbidity test had become reduced from 4+ to 2+ and the cephalin flocculation test, which before operation had been consistently strongly positive, had returned to normal.

This case has been cited in some detail to illustrate two additional points namely (1) Results of tests designed to indicate liver damage and/or impairment of function do not

TABLE I

No patal o	Preoperative liver chemistry	Postoperative course
1 171	Cephalin flocculation 4+ serum albumin 2.9% globulin 3.7% serum bilirubin 2.7 mgm % serum phosphatase 0.5 B U % bromsulfalein retention 1/2 hr 70%	Anorexia weakness temporary recurrence of ascites
2 1996	Cephalin flocculation 3+ serum albumin 3.3% globulin 5.7% serum phosphatase 10.7 B U % serum bilirubin 1.9 mgm % hippuric acid excretion 0.8 gm bromsulfalein retention 1/2 hr 42%	Ascites reappeared requiring one paracentesis Wound disrupted
3 1765	Cephalin flocculation, 3+ serum albumin 3.5% globulin 2.9% serum phosphatase 6.1 B U % serum bilirubin 1.3 mgm % bromsulfalein retention 45 min after injection 23% prothrombin time 50% of normal	Ascites reappeared transiently
4 2015	Cephalin flocculation 4+, thy mol turbidity 4+ serum albumin 3% globulin 2.9% serum bilirubin 3.6 mgm % serum phosphatase 3.9 B U % galactose removal constant, 2.1 bromsulfalein retention 45 min 37% prothrombin time 60% of normal	Ascites occurred on 3rd postoperative day requiring 1 paracentesis
5 1905	Cephalin flocculation, negative serum albumin 2.9% globulin 2.3% serum phosphatase 3 B U % bromsulfalein retention 1/2 hr, 35%	Ascites recurred and persisted for several months finally disappearing as the serum proteins rose
6 7310	Cephalin flocculation negative serum albumin 3% globulin 2.3% serum bilirubin 2.5 mgm % serum phosphatase 4.6 B U % bromsulfalein retention 1/2 hr after injection 40%	Ascites reappeared but proved transitory. Became more jaundiced for a week postoperatively
7 3972	Cephalin flocculation, negative serum albumin 2.3% globulin 3% serum phosphatase 10.2 B U % hippuric acid excretion, 0.6 gm bromsulfalein retention 1/2 hr 40%	Anorexia weakness Recurrence of ascites requiring 1 paracentesis on 8th postoperative day

rays correlate well with the pathologist's interpretation of disease on the basis of microscopic examination of fixed and stained sections taken from a biopsy specimen of the liver. (2) Discrepancies occur between the surgeon's report on the gross examination of the liver and the pathologist's report on the microscopic examination of a biopsy specimen. The pathologist's report on the biopsy specimen of this girl's liver was as follows: "fatty infiltration, more marked in the peripheral areas. No cellular infiltration and but little fibrosis." The facts of the matter are that the pathologist did not see enough evidence upon which to base the diagnosis of cirrhosis and the biopsy specimen was classified as "undiagnosed condition of the liver."

The surgeon's observations at operation are decidedly in keeping with the long clinical history, the physical findings, and the laboratory studies in this case. The right lobe of the liver was contracted and its surface studded with irregular sized nodules. The consistency was abnormally firm. The left lobe was enlarged but otherwise appeared normal on gross examination. A portal pressure reading taken from the splenic vein revealed the presence of portal hypertension.

The cephalin flocculation reaction is interpreted by many to indicate active liver cell injury in cases of cirrhosis of the liver. Hanger and Patek's observations are of interest.¹ These authors correlated the cephalin flocculation and the clinical course of 40 patients having cirrhosis of the liver. The cephalin flocculation reactions were consistently strongly positive (3+ to 4+) in 17 per cent of the 40 cases. Twelve of the 17 patients died and 4 additional had a clinical course that was classified as unfavorable or stationary, in only 1 case was the clinical course favorable. In 12 of the 40 patients the cephalin flocculation reaction was progressively diminishing. This group had a decidedly more favorable clinical course. Only 3 patients died, the remaining 9 having a favorable clinical course. Finally, there were 11 of the 40 who had a persistently weak or negative flocculation reaction. Three patients died in this group and 8 had a favorable clinical course.

In our series of 44 patients having disease of the liver in which the portacaval anastomosis operation was performed there were 10 postoperative deaths. It is of interest to note that the cephalin flocculation reaction was strongly positive (3+ to 4+) in 8 of the 10 cases. In 1 case, the test was not recorded as having been done and in 1 case the test was weakly positive.

It must be remembered, however, that in the group of postoperative deaths, the liver played no role in the cause of death in at least 3 of the 10 deaths. Furthermore, one must keep in mind that whereas the cephalin flocculation reaction is important it can present but one part of the total picture in the preoperative evaluation of the status of the

¹HANGER, FRANKLIN M. and PATEK, ARTHUR J. Jr. *Am J M Sc.* 1941 202 48 57.

liver. This is well illustrated by the fact that 11 of the 20 patients with strongly positive cephalin flocculation reactions did withstand the portacaval shunt procedure successfully.

To obtain an over-all perspective of the relative values of the different liver tests employed in terms of the postoperative behavior of the liver, it is well perhaps to illustrate with cases. I have selected 7 patients whose postoperative course for a short while was punctuated by unmistakable evidence of further depression of liver function even though they had survived the portacaval shunt procedure.

Table I shows the preoperative liver studies and the postoperative comments on the 7 cases. In respect to the latter it is to be noted that ascites appeared postoperatively in all 7 cases. Ascites occurring during the postoperative course in a patient whose portal hypertension has been relieved through the establishment of a portacaval shunt is interpreted by us to mean unmistakable clinical evidence of severe depression of liver function.

One is impressed by one fact in comparing the array of liver studies in the different cases, namely, the importance of no single test to the exclusion of others. The best example of this is the cephalin flocculation reaction which is strongly positive in 4 cases and totally negative in 3. I am inclined to believe, however, that the type of cirrhosis is a factor in this particular discrepancy. The 3 instances of negative flocculation tests were in cases of Laennec's cirrhosis, whereas, in our opinion, in 3 of the 4 cases of strongly positive cephalin flocculation reactions, the cirrhosis was of the posthepatitis variety.

Any positive advantage of the negative cephalin flocculation reaction in Cases 5, 6, and 7, would seem to be well offset by extreme-

ly low albumin percentages and the marked impairment on the part of the liver to excrete bromsulfalein. The serum bilirubin is noted to be elevated in 5 of the 7 cases.

By all odds the patient in Case 4 has the worst over-all picture and, with the exception of 1 patient (Case 5), she had the stormiest postoperative course.

The most consistent findings throughout the series of 7 cases is the marked inability of the liver to excrete bromsulfalein and make albumin. The quickest postoperative deaths from liver failure in our experience occurred in 2 patients each of whom preoperatively had a serum albumin level of 2.4 per cent. One patient was in coma and died on the second postoperative day with a blood nonprotein nitrogen of 136 milligrams per cent. The other patient died in coma on the fourth day with a blood urea of 74 milligrams per cent. One of the patients had a severe unremitting jaundice and the other had a bromsulfalein retention of 40 per cent $\frac{1}{2}$ hour after injection.

CONCLUSIONS

Our experience would indicate that patients with cirrhosis, who have serum albumin levels of 3 per cent or under with bromsulfalein retention in excess of 35 per cent $\frac{1}{2}$ hour after injection, are in general not good operative risks. Careful study of individual cases, however, will reveal, even in this group, a wide margin of risk. Particularly is this true in posthepatitis cases. It is remarkable how many of these patients can be brought through a shunt procedure safely if care is exercised in the selection of the time to operate, the preoperative preparation, and the postoperative handling.

THE EFFECT OF REDUCED BLOOD FLOW TO THE LIVER IN RENAL HYPERTENSION

LOYAL DAVIS, M D , F A C S , CARLOS TANTURI, M D , and
JOSEPH TARKINGTON, M D , Chicago, Illinois

THE modern theories concerning the causative factors of vascular hypertension and of their interrelationships may be stated as follows

(A) Renin, a protein-like substance, is formed in excessive amounts by an "ischemic" "anovemic" renal parenchyma. Hypertensinogen, the precursor of hypertensin, is an alpha-globulin substance formed in the liver and has a specificity for reacting with renin, produced in the kidney, to form hypertensin, the vasopressor substance

(B) The existence of a hitherto undescribed homeostatic system for the regulation of the peripheral circulation has been disclosed in recent studies (3) "This system is made up of two components, one of hepatic (V D M), the other of renal origin (V E M). Evidence of the presence of such a circulatory homeostatic system, its mode and sites of origin, and the manner in which it regulates the behavior of the peripheral vascular bed, was first derived from studies on experimental hemorrhagic and traumatic shock. Subsequent studies have shown this homeostatic system to be likewise involved in the syndrome of experimental renal hypertension." The most probable mechanism responsible for the formation of these vasotropic factors during the shock syndrome is, as was pointed out, the reduced oxygen tension resulting from the reduction in blood flow to the liver and skeletal muscle (V D M), and the kidney (V E M)

Since it has been demonstrated that the plasma level of hypertensinogen is maintained by its production in the liver, and since a decrease in hypertensinogen is described only in some cases of experimental acute liver insufficiency (2), we have attempted to produce low grade hepatic pathology to inhibit the

formation of hypertensinogen, and thereby relieve an experimentally produced hypertension. On the other hand, reducing the blood flow to the liver should increase the formation of the vasodepressor factor considered to play a role in the homeostatic system involved in the syndrome of experimental renal hypertension

To date, we have produced renal hypertension in 5 dogs by the Goldblatt and Grollman methods and subsequently have partially occluded their hepatic arteries and portal veins to cause a relative anoxemia of the liver parenchyma. Goldblatt clamps were used to maintain a uniform and consistent caliber of the vessels. We have found a substantial reduction in the systolic blood pressure of each of the 5 animals following the reduction of the blood flow to the liver. Three of these experiments are summarized in Table I. The renal hypertension was induced by clamping the renal arteries with Goldblatt clamps, or by compressing one kidney and removing the other in a two stage operation according to the method of Grollman. In our experience, the Goldblatt procedure produces an earlier rise and a better sustained hypertension in dogs than does the Grollman technique

A Goldblatt clamp was placed on the portal vein at the entrance of the vessel into the liver above the splenic vein. The lumen of the clamp, when it is completely open and in place, is enough to reduce about one-half to two-thirds of the portal flow without producing symptoms in the animal. Another Goldblatt clamp was placed on the common hepatic artery after infiltration of the periarterial tissue with procaine solution. The hepatic plexus which surrounds the artery was carefully stripped off, this procedure avoided the vasoconstriction produced by manipulating the artery and leaves the caliber of the vessel normal. This step is essential in order to place

TABLE I—SUMMARY OF 3 EXPERIMENTS

Dog	Renal surgery	Blood pressure	Partial occlusion of portal vein and hepatic artery	Blood pressure	Course
9	5-13-48 Bilateral Goldblatt clamps	6-8-48 180 mm Hg	6-8-48 Prothrombin concentration 7-16-48 90% 7-23-48 90% 7-23-48 70% 9-24-48 80% 11-10-48 90%	6-17-48 150 mm Hg 6-19-48 130 mm Hg	Portacaval shunt, 12-3-48 Biopsy of liver 12-3-48 Blood pressure 138 mm Hg
15	7-16-48 Bilateral Goldblatt clamps Prothrombin concentration preoperatively 100%	7-27-48 175 mm Hg Prothrombin concentration 7-23-48 110%	7-30-48 Hepatic artery clamp adjusted 9-1-48 Prothrombin concentration 7-30-48 80%	8-11-48 190 mm Hg 8-23-48 150 mm Hg 8-31-48 170 mm Hg 9-3-48 150 mm Hg Prothrombin concentration 11-10-48 90%	Blood pressure has remained at 150 mm Hg for 120 days
18	Grollman method 8-4-48 Left kidney compressed by figure of 8 ligature 8-20-48 Right kidney removed	8-31-48 180 mm Hg	9-9-48 Prothrombin concentration 9-22-48 100%	9-14-48 140 mm Hg 10-12-48 80 mm Hg 11-9-48 120 mm Hg Prothrombin concentration 10-18-48 90% 11-10-48 80%	Blood pressure has remained at 120 mm Hg for 111 days Portacaval shunt 12-29-48

the clamp and adjust it to obtain a uniform reduction of the lumen of the vessel. For this purpose, the screw of the Goldblatt clamp is completely tightened down and then one complete turn to release it is made.

After the operation the dogs showed no symptoms of illness. They remained alert and ate normally although most of them lost weight. A portal hypertension developed at the end of 2 to 3 months evidenced by dilatation of the veins in the abdominal wall. The liver showed a bright yellow color with a distinct lobular pattern. Fluid was not present in the peritoneal cavity. Histological studies of the liver will be reported upon elsewhere. Prothrombin determinations of the plasma were made periodically to detect any degree of liver injury produced by the reduced liver circulation. Variations between the normal limits always were found although some may be considered as low normal. One dog showed a reduction of 50 per cent.

In 2 dogs 130 and 111 days after the operation, a portacaval anastomosis was performed to relieve the portal hypertension and to observe the effect on the arterial blood pressure of diverting the apparently increased blood volume of the splanchnic area. To date no change in the arterial blood pressure has been

observed 30 and 20 days after this operation (Table I).

Work is in progress to investigate whether reduction of the hepatic or portal circulation is more important. Preliminary results show that by ligating the branches of the hepatic artery that enter the liver, a steady decline of systolic blood pressure is obtained in hypertensive dogs (Goldblatt type)¹. Experiments are also under way to determine if the surgical procedure of reducing the blood flow to the liver interferes with the production of hypertensinogen or increases the formation of the vasodepressor substance of Shorr, Zweifel, Furchgott, and Balz (V D M).

¹Ligation of the liver branches of the hepatic artery in the normal dog have long been known to result in death within 24 to 36 hours. If penicillin is given immediately following the ligation the dogs live. This latter experiment has been carried out in our laboratory for the past 6 months. Markowitz, Rappaport and Scott (3) learned the same fact independently and have reported their result.

THE EFFECT OF REDUCED BLOOD FLOW TO THE LIVER IN RENAL HYPERTENSION

LOYAL DAVIS, M D, F A C S, CARLOS TANTURI, M D, and
JOSEPH TARKINGTON, M D, Chicago, Illinois

THE modern theories concerning the causative factors of vascular hypertension and of their interrelationships may be stated as follows

(A) Renin, a protein-like substance, is formed in excessive amounts by an "ischemic" or "anovemic" renal parenchyma. Hypertensinogen, the precursor of hypertensin, is an alpha-globulin substance formed in the liver and has a specificity for reacting with renin, produced in the kidney, to form hypertensin the vasopressor substance

(B) The existence of a hitherto undescribed homeostatic system for the regulation of the peripheral circulation has been disclosed in recent studies (3) "This system is made up of two components, one of hepatic (V D M), the other of renal origin (V E M). Evidence of the presence of such a circulatory homeostatic system, its mode and sites of origin, and the manner in which it regulates the behavior of the peripheral vascular bed, was first derived from studies on experimental hemorrhagic and traumatic shock. Subsequent studies have shown this homeostatic system to be likewise involved in the syndrome of experimental renal hypertension." The most probable mechanism responsible for the formation of these vasotropic factors during the shock syndrome is, as was pointed out, the reduced oxygen tension resulting from the reduction in blood flow to the liver and skeletal muscle (V D M), and the kidney (V E M)

Since it has been demonstrated that the plasma level of hypertensinogen is maintained by its production in the liver, and since a decrease in hypertensinogen is described only in some cases of experimental acute liver insufficiency (2), we have attempted to produce low grade hepatic pathology to inhibit the

formation of hypertensinogen, and thereby relieve an experimentally produced hypertension. On the other hand, reducing the blood flow to the liver should increase the formation of the vasodepressor factor considered to play a role in the homeostatic system involved in the syndrome of experimental renal hypertension

To date, we have produced renal hypertension in 5 dogs by the Goldblatt and Grollman methods and subsequently have partially occluded their hepatic arteries and portal veins to cause a relative anoxemia of the liver parenchyma. Goldblatt clamps were used to maintain a uniform and consistent caliber of the vessels. We have found a substantial reduction in the systolic blood pressure of each of the 5 animals following the reduction of the blood flow to the liver. Three of these experiments are summarized in Table I. The renal hypertension was induced by clamping the renal arteries with Goldblatt clamps, or by compressing one kidney and removing the other in a two stage operation according to the method of Grollman. In our experience, the Goldblatt procedure produces an earlier rise and a better sustained hypertension in dogs than does the Grollman technique

A Goldblatt clamp was placed on the portal vein at the entrance of the vessel into the liver above the splenic vein. The lumen of the clamp, when it is completely open and in place, is enough to reduce about one-half to two-thirds of the portal flow without producing symptoms in the animal. Another Goldblatt clamp was placed on the common hepatic artery after infiltration of the periarterial tissue with procaine solution. The hepatic plexus which surrounds the artery was carefully stripped off, this procedure avoided the vasoconstriction produced by manipulating the artery and leaves the caliber of the vessel normal. This step is essential in order to place

From the Department of Surgery, Northwestern University Medical School, aided by a grant from the Lois Grunow Surgical Fund.

TABLE I—SUMMARY OF 3 EXPERIMENTS

Dog	Renal surgery	Blood pressure	Partial occlusion of portal vein and hepatic artery	Blood pressure	Course
9	5-13-48 Bilateral Goldblatt clamps	6-8-48 180 mm Hg	6-8-48 Prothrombin concentration 7-16-48 90% 7-23-48 90% 7-23-48 70% 9-24-48 80% 11-10-48 90%	6-17-48 150 mm. Hg 6-19-48 130 mm Hg	Portacaval shunt 12-3-48 Biopsy of liver 12-3-48 Blood pressure 138 mm Hg
15	7-16-48 Bilateral Goldblatt clamps Prothrombin concentration preoperatively 100%	7-27-48 175 mm. Hg Prothrombin concentration 7-23-48 110%	7-30-48 Hepatic artery clamp adjusted 9-1-48 Prothrombin concentration 7-30-48 80%	8-11-48 190 mm Hg 8-23-48 150 mm Hg 8-31-48 170 mm Hg 9-3-48 150 mm Hg Prothrombin concentration 11-10-48 90%	Blood pressure has remained at 150 mm Hg for 120 days
18	Grollman method 8-4-48 Left kidney compressed by figure of 8 ligature 8-20-48 Right kidney removed	8-31-48 180 mm Hg	9-9-48 Prothrombin concentration 9-22-48 100%	9-14-48 140 mm Hg 10-12-48 80 mm Hg 11-9-48 120 mm Hg Prothrombin concentration 10-18-48 90% 11-10-48 80%	Blood pressure has remained at 120 mm Hg for 111 days Portacaval shunt 12-29-48

the clamp and adjust it to obtain a uniform reduction of the lumen of the vessel. For this purpose, the screw of the Goldblatt clamp is completely tightened down and then one complete turn to release it is made.

After the operation the dogs showed no symptoms of illness. They remained alert and ate normally although most of them lost weight. A portal hypertension developed at the end of 2 to 3 months evidenced by dilatation of the veins in the abdominal wall. The liver showed a bright yellow color with a distinct lobular pattern. Fluid was not present in the peritoneal cavity. Histological studies of the liver will be reported upon elsewhere. Prothrombin determinations of the plasma were made periodically to detect any degree of liver injury produced by the reduced liver circulation. Variations between the normal limits always were found although some may be considered as low normal. One dog showed a reduction of 50 per cent.

In 2 dogs 130 and 111 days after the operation, a portacaval anastomosis was performed to relieve the portal hypertension and to observe the effect on the arterial blood pressure of diverting the apparently increased blood volume of the splanchnic area. To date no change in the arterial blood pressure has been

observed 30 and 20 days after this operation (Table I).

Work is in progress to investigate whether reduction of the hepatic or portal circulation is more important. Preliminary results show that by ligating the branches of the hepatic artery that enter the liver, a steady decline of systolic blood pressure is obtained in hypertensive dogs (Goldblatt type).¹ Experiments are also under way to determine if the surgical procedure of reducing the blood flow to the liver interferes with the production of hypertensinogen or increases the formation of the vasodepressor substance of Shorr, Zweifach, Furchgott, and Balz (V D M).

¹Ligation of the liver branches of the hepatic artery in the normal dog have long been known to result in death within 24 to 36 hours. If penicillin is given immediately following the ligation the dogs live. This latter experiment has been carried out in our laboratory for the past 6 months. Marlowitz, Rappaport, and Scott (3) learned the same fact independently and have reported their result.

THE RH FACTOR

THE discovery of this constituent of human blood by Landsteiner and Wiener in 1940 and the further studies carried out by Wiener and his associates, by Levine and his coworkers, by Edith Potter, by Diamond, and by Hill and Haberman, of this country, have aided in the clarification of previously unexplainable transfusion reactions and in solving the mystery of hemolytic disease of the newborn (commonly called erythroblastosis fetalis). Noteworthy contributions to this subject have also been made by Coombs, Race, Taylor, Fisher and Mourant, of England, and by Chown, of Canada.

The Rh factor is really a complex, composed of the subgroups Rh₀, Rh', and Rh". Eighty-five per cent of Caucasians possess the Rh₀ factor along with one or both the others, about 3½ per cent possess only one factor, and about 13 per cent lack all 3 factors. The latter are the true Rh negative persons, though this term is universally applied to those lacking the Rh₀ factor. In other races

98 per cent or more possess the Rh factor, and it has been suggested that those who do not probably have an admixture of white blood.

The Rh factor acts as an antigen and may stimulate the production of antibodies if introduced into the blood of an Rh negative individual. This may be accomplished by blood transfusion or by pregnancy produced in an Rh negative woman by an Rh positive man. Here the red blood cells evidently pass from fetus to mother through microscopic lesions in the placenta, probably seeping through all during the pregnancy. Some contend, however, that this transfer occurs most often during labor. At any rate, it appears that in pregnancy the process of antibody formation is a gradual one, so that in the first pregnancy they cannot be detected. Once the antibodies are formed, they may cross the placental barrier from mother to child in a subsequent pregnancy and attack the red cells carrying the Rh factor, thus producing hemolytic disease. Three types can be differentiated clinically, the hydropic (mortality, nearly 100 per cent), the icteric (40 to 50 per cent fatal), and the anemic (with a risk of 15 to 20 per cent). The infant may die in the uterus days or weeks before delivery, may die shortly after birth, or may survive, especially when promptly and properly treated. Once sensitization of a woman is established, it persists throughout life, and if she has lost a child from hemolytic disease, all subsequent Rh positive children borne by her will suffer the same fate. However, this mother-to-child antibody transfer does not always occur, or it may be so slight as to be of no consequence. Furthermore, about 50 per cent of such women are not capable of sensitization.

These antibodies may be of the type that cause agglutination of the red cells in saline, or they may be of the "blocking" or "incomplete" variety which prevent or "block" the agglutinating property of the first type because of their greater affinity for the combining units on the red cells. They agglutinate Rh positive cells in a protein medium. They result from more prolonged immunization, and may ultimately replace the simple antibodies, hence their presence, especially if found alone and in high titer, establishes a more serious (but by no means is this infallible) prognosis for the present, or any future infant. If one or both antibodies are found persisting in the maternal blood months or years after delivery, the outlook in a future pregnancy is especially somber.

Of the 15 per 100 females who are Rh negative, some are not in the childbearing age, some are not married, and a few are married to Rh negative men. Hence only about 9 per cent of all pregnancies occur in Rh negative women married to Rh positive men, and, as noted above, many of these women are not susceptible of sensitization. Furthermore, about 58 per cent of Rh positive men are heterozygous for the Rh factor, hence that percentage of their children should be Rh negative. Thus, only in about 1 to 350 (some say 1 to 500) deliveries will the child be affected in varying degree with hemolytic disease of the newborn. This will not occur in the first term pregnancy unless the mother has been sensitized by blood transfusion or by a pregnancy which has progressed to 4 or 5 months or more before abortion occurred. The disease is most often noted in the second or third and subsequent pregnancies, rarely not until the fifth or sixth. In 569 consecutive patients in our private practice, our group found 98, or 17.3 per cent, of the women to be Rh negative. Of these, the potentiality of Rh

sensitization was present in 43. In 24 women it did not develop, in 10 it was found, 8 were still undelivered and in 1 the outcome was not known. Of the 10 women, 6 lost a total of 8 babies. Thus, 1.05 per cent of these 569 women lost their babies from hemolytic disease. This is much higher than the ratio usually given.

Three Hr factors, the reciprocals of the corresponding Rh factors, have been found. Of these, only the Hr' is capable of producing antibodies, and that very rarely. Davenport of New Orleans, in thousands of studies, has found only 1 such case, a quadron at the Charity Hospital.

As stated, once sensitization is established, it is permanent. The recent work with the haptens by Carter offers great promise of combatting this, but much remains to be done. At present, 15 to 30 liters of blood must be processed to secure enough haptens to desensitize one patient. Phillipot has suggested the use of methionine, 5 grams daily, throughout pregnancy for its protective influence on the fetal liver, the organ chiefly affected. This may be of value, but definite conclusions cannot be drawn from the few cases so far reported.

As far as transfusion is concerned, the clinical implication is clear. Rh typing should be routine, and no Rh negative person, male or female, should receive Rh positive blood. If this has been done, either in the days before the Rh factor was known, or in case of great urgency, that patient should under no circumstances be transfused again with Rh positive blood. The risk of a fatal reaction would be too great.

In obstetrical practice the Rh type of every pregnant woman should be determined early. If she is Rh negative and has had a transfusion, the Rh type of the transfused blood should be ascertained if possible. Also, the Rh

status of her husband and of other children (if any) should be determined. If she is a multigravida, or if she is a primigravida with a history of transfusion, tests for antibodies should be done at monthly intervals after the fifth month, and if present, titers should be noted. In such a case the prognosis for the child should be guarded, especially if the titer is rising, a rising titer of blocking antibodies is considered particularly grave. We cannot be too dogmatic, however, for we have all had the experience of delivering perfectly normal Rh negative babies under such conditions.

The termination of pregnancy 3 or 4 weeks before term by cesarean section or by induction of labor has not given satisfactory results in our hands, or in the experience of others. The babies are either severely damaged already, or they are in good condition. In either instance, the hazard of prematurity is an added risk.

After delivery, the Rh type of the baby and a study of its blood should be performed at once. If the baby is Rh positive, and is jaundiced or anemic with an abnormally high percentage of erythroblasts, transfusion with Rh negative blood should be performed at once. The same is true if the baby is Rh negative, and the clinical picture is that of hemolytic disease. In such a case, the true Rh type may be masked by the presence of antibodies, or the trouble may be caused by another type of sensitization. If the baby appears normal, it should be very closely observed clinically, and with hourly blood studies, and transfused as soon as any abnormal developments are noted. We prefer the replacement transfusion, using the umbilical vein if done soon after birth, the femoral if done later. The long plastic catheters of Diamond are employed, injecting 30 cubic centimeters at a time, then withdrawing 30 cubic centimeters, injecting and withdrawing again, and continuing this

until 350 to 500 cubic centimeters of blood have been used. We consider this preferable to the use of repeated small transfusions, however, these have been used successfully in many cases.

It is important to discuss the situation frankly with the parents. One should not be overly optimistic or unduly pessimistic. As yet we do not know enough to be dogmatic in our statements.

ACUTE FULMINATING CHOLECYSTITIS

NOT many decades have passed since the surgeon, faced with the problem of acute fulminating cholecystitis, thought only of the establishment of a vent to the outside world through which the distended gall bladder could empty. It was quite likely that, on account of inadequate anesthesia and other factors, an all-important stone in the cystic duct, or a large one impacted in the ampulla, might be left in place, and that the fistula of the cholecystostomy would fail to close. Over the years general advances in surgery, and a better understanding of the nature of acute cholecystitis, have led to the general acceptance of prompt cholecystectomy as the procedure of choice in the average case. Twenty years ago it was the custom to let acutely inflamed gall bladders "cool off," and to wait a few days after the patient's temperature reached normal before proceeding with surgery. In many instances the process advanced to perforation instead of subsiding. In addition, it was found that operation was likely to be technically much easier early in the acute phase than it would be ten days later. Endless arguments ensued between surgeons who advocated "immediate" operation and those who considered this unwise. Much of the difference of opinion was

due to the loose use of terms and misunderstanding as to just what "early" or "immediate" meant, in relation to the onset of the attack, or to the patient's admission to the hospital

Acute cholecystitis is a dramatic disease and the appearance of the gall bladder at operation may be alarming indeed, with the huge thick red viscus often extending well down into the right lower quadrant or well out toward the flank. Fortunately, the pathology is usually not as ominous as it looks. Real empyema is the exception rather than the rule. Stones are almost invariably present, and distention of the gall bladder follows obstruction. The vascular factor then becomes important, with interference with the cystic vein and then the artery. The bacterial factor may be relatively in the background for some time. The omentum is a great shield against free perforation but perforation occurs often enough to present a real hazard. For some unknown reason acute cholecystitis seems to be commoner in males. The more treacherous and rapidly progressing type is apt to be encountered in the older age groups.

There seems not the slightest doubt that the swing of the pendulum to prompt cholecystectomy in these patients represents real progress and a very fortunate trend. However, those who are teaching young surgeons have the responsibility of pointing out repeat-

edly that there is still a definite place for cholecystostomy in the management of certain cases. Removal of an acutely inflamed gall bladder may be surprisingly simple and easy. On the other hand, engorgement, distortion, or friability may preclude the careful and complete demonstration of structures that is so essential to performance of a safe cholecystectomy.

Just as it is wise in occasional cases of appendicitis with abscess merely to establish drainage and to leave the removal of the appendix to a future date, so is it wise in certain cases of fulminating cholecystitis to limit the surgery to a careful cholecystostomy. One should never be ashamed when confessing this conservative decision to the patient or the family. If great care is taken to empty the gall bladder completely and external bile drainage appears promptly a most encouraging proportion of these patients remain well indefinitely after cholecystostomy.

If one is reasonably sure, at operation, that cholecystectomy can be safely accomplished it is surely the procedure of choice. In all other instances (probably 15 to 20 per cent) cholecystostomy should be resorted to. The decision must be made promptly and not *after* getting into serious technical difficulties. They are likely to be the sort of difficulties that are very hard indeed to get out of.

THE BOOK SHELF

THE BIRTH OF AN EMPEROR

RUDOLPH MARX, M D, F A C S, Los Angeles, California

IN the Crown Prince's Palace at Berlin on the night of January 26, 1859, there was hushed excitement. Victoria Louise, daughter of Queen Victoria of England and wife of the Crown Prince of Prussia, was expecting her first child—the heir apparent of Prussia.

The large chamber of the Crown Princess was being used as the delivery room according to the custom of the times. In a corner an old maid-servant tended a wood fire in a large white porcelain stove. Outside an icy blizzard drove large flakes of snow across the Avenue, Unter den Linden. Again and again the shrieking storm, muffled by the heavy window curtains, pierced the stillness of the room and made the timid little flames of the candles shiver in their glass chimneys on the wall. Their soft reflections danced in the glass of several small pictures whose gay colors tried vainly to brighten the austerity of the high walls. These were water colors painted by the talented young princess herself. Pathetically incongruous they looked amidst the heavy draperies and carved furniture of the room—a futile attempt of the English girl to introduce a personal note into the frigid formality of her surroundings.

Beneath the heavy coverings of a huge canopied four-poster bed lay Victoria, almost hidden, a slender girl with blond hair and gray-blue eyes, a fine, slightly upturned nose and proud lips. No utterance of pain showed that she was in labor. With the self-control inculcated from childhood, she was bearing up silently as the relentless waves of pain passed through her body.

In a heavy armchair at the bedside sat the doctor, Professor Martin, the famous chief of the school of midwifery at the Hospital Charite of Berlin. The prototype of the doctor of his day, he was about forty, wore side-whiskers and frock coat, and had brown hair thinning at the temples. Early that morning he had arrived at the palace with his staff of doctors, midwives, and nurses.

Now he sat motionless, his keen gray eyes under a deep frown of worry fixed on the expectant mother.

Only once before this day had he been permitted to examine the Crown Princess, and then only through her heavy clothing. Upon his arrival at the palace in the morning he had made a thorough examination—the findings had confirmed his worst suspicions. The position of the infant was abnormal. Instead of the head, the buttocks were poised above the pelvis. This complication, known as breech presentation, happened about once in thirty births, and was fraught with danger. Especially in a firstborn.

The doctor had tried to correct the wrong position by external version, the procedure which he had been one of the first to describe in medical literature. He had attempted to turn the infant in the womb by deep manipulation from the outside. The doctor's skilled hands, feeling the contour of the child through the abdomen, tried to shove the trunk of the baby to one side and up, at the same time pushing the head down into its proper place in the pelvis.

To relax the tense muscles of the patient, the doctor had even employed chloroform, which had been in use as an anesthetic for only ten years. But all his efforts had been in vain. The infant was apparently too large to be turned, its head too big to be accommodated in the pelvis of the small mother. During the anesthesia the doctor had also found that the birth canal had not yet widened enough to permit a manual extraction of the child.

All day long and into the night, unable to do anything further, the doctor had sat at the bedside of the princess, anxiously waiting upon the intolerably slow natural progress. He could not even relieve the travail of the expectant mother by continuing the anesthetic. The danger of chloroform for mother and child when kept up for

Ewing Galloway N.Y.

Birthplace of Wilhelm II of Germany—Crown Prince Palace, Unter den Linden, Berlin

a longer period was already known, as was also its paralyzing effect upon the spontaneous progress of labor

As the night wore on the labor pains became more frequent and severe. Finally the girl of eighteen, who had borne up for so many hours with heroic self-control, broke down. Her lips quivered, tears filled her eyes, and like any girl of her age, she cried for her mother. But the devoted mother, Queen Victoria of England, for reasons of State, could not be present. In her stead she had sent the girl's old governess to act as faithful companion and first lady-in-waiting. This little English baroness now leaned over the bed and stroked the young girl's cheek, murmuring tender words with restrained affection.

Suddenly a rustling was heard in the anteroom. Princess Augusta, wife of the Prince Regent and mother of the Crown Prince, was approaching. As she entered the room, followed by her lady-in-waiting, everyone rose and bowed.

The older princess leaned over the girl in the bed and spoke to her gently. Then she turned to the doctor and motioned him aside. In low tones the doctor told her the result of his examination

and explained the difficulties and dangers of the confinement. The only good word he could bring was the fact that his findings had revealed the baby to be a boy. Excitedly the old princess hurried out to carry the good and the bad news to her son, the blond young giant, Frederic Wilhelm of Hohenzollern, who like any other prospective father, was pacing the floor outside the room.

In a dark corner at the head of the bed, tall and motionless, stood the second lady-in-waiting, an old Prussian countess. Her black gown melted into the shadows of the heavy plush curtains on the canopied bed. Only her sharp white profile was visible in the dim light. With aquiline nose, jutting chin and stern mouth, she looked like a painting of one of her Crusader ancestors. She was of the oldest and proudest nobility of Prussia. The founder of her family, a famous Teutonic knight, had wrested the wilderness of East Prussia from the native Slavs in many a bloody battle.

Like other members of the old nobility of East Prussia, the countess looked with secret disdain upon the Hohenzollerns as newcomers and upstarts. Whereas the Teutonic knights had lived and died in Prussia since the 12th Century, the

Hohenzollerns, of undistinguished South German nobility, had not appeared until the 15th Century in Brandenburg. They had only acquired East Prussia in the 17th Century in a marriage bargain.

Now these new masters had given the Prussian nobility fresh cause for resentment. They had ignored the noble families of their own country and chosen a foreign bride for their Crown Prince.

The old countess had been watching the proceedings in the room all day with no sign of emotion. Her ears, sharpened by a lifetime of listening to the whispers of the Court, had overheard the low conversation between the doctor and the old princess.

Now she stepped forward and motioned the English baroness aside. Gravely she inquired if the baroness had heard the professor's bad news? Now she understood the dark rumors that had reached the palace from the royal court. The ghost of the "white lady" had been last night seen in the old palace at Potsdam. This apparition forbode evil to the house of Hohenzollern. The face of the little Englishwoman grew pale with anger and indignation.

"Spare me your silly superstitions and old fairy tales! You like to believe them because you hate us and wish us ill."

In a cold voice the countess answered, "But I tell you that they are not fairy tales. It is an evil omen for a child to be born breech first. Man is ordained to come into the world with his head leading. Creatures who enter the world by their extremities are possessed of base instincts."

With a gesture toward the bed the baroness tried to hush her, but the old Prussian woman would not be silenced. "Children brought forth by their feet are cursed—they are born as monsters, crippled in mind and body, and destined to bring misfortune into the world. It would be better if they were not born." Anxiously the Englishwoman searched the face of Victoria Louise, but the expectant mother, absorbed by her all-important task, was oblivious to everything outside of her.

The doctor looked up startled as snatches of the conversation reached his ears. His eyes met the cold gaze of the tall lady in black as she slowly retired into the dark corner. The doctor was well aware of the popular superstition that had survived since the Dark Ages about babies born feet first. Such children were believed to be possessed of the devil. And only too well did he know the facts on which the superstition was based. He could not help pondering the perils which this infant was facing during its journey into the world. He knew that almost one-third of firstborns de-

livered in this way were doomed to die. Of the remainder, many were crippled during birth and frequently in later life showed consequences of injury suffered during birth.

Reflecting on these dark prospects the doctor felt like a doomed man as he sat helplessly at the bedside. His was the superhuman task of solving a problem at which nature seemed to be failing. Put into his human hands was the fate of the heir of the great dynasty of the Hohenzollerns. How could a mere mortal bear the crushing burden of so great a responsibility? A silent prayer moved his lips.

The head midwife who had been listening to the heart sounds of the infant through the primitive wooden stethoscope, now motioned to the doctor. He took the stethoscope and listened. Under the continuous pressure of labor, the heart sounds of the child had become irregular—a signal of distress. The doctor checked the progress of labor and found that even after so many hours, the birth canal was still not dilated enough to allow a safe manual extraction of the child. But the ominous change of the infantile heart sounds left him no choice. There was no time to be lost if the child was to be saved. Hurriedly he consulted with his assistants and ordered everything to be made ready for an immediate manual delivery.

The first assistant started to drop chloroform on a mask covering the nose and mouth of the princess. The doctor and second assistant removed their frockcoats and turned up their shirt sleeves. A nurse tied aprons on them and they gave their hands a cursory wash, drying them on linen towels. Pasteur and Lister had not yet made their discoveries and the science of antiseptics was not born. The narcotized woman was placed on a marble table covered with sheets. The assistant administered the chloroform cautiously, drop by drop, aware of the narrow margin between the sleep-producing and the lethal dosage. The princess was still moving in her sleep as the doctor started his work of extracting the child.

He felt a leg and pulled on it. The left foot appeared. He succeeded in freeing the second leg without difficulty. Now he drew steadily on both legs and soon the slippery trunk emerged, the navel became visible. Quickly he loosened the tightened cord which carried the life-giving oxygen from mother to infant.

The real danger was now at hand. As the shoulder blades began to emerge, the head which followed began to encroach upon the cord, shutting off the circulation to the child. The doctor glanced at the clock on the wall impersonally ticking off the seconds. If the infant was to be born un-

harm, the doctor knew that he must complete the delivery within the next eight minutes. The brain would not be able to withstand the lack of oxygen longer without risk of permanent damage or even death.

The doctor was breathing heavily as he looked anxiously at the clock again and again. Perspiration dripped down his face and collected in drops upon his whiskers.

Now a further complication arose. During the extraction of the baby the arms had been pulled upward about the head, further reducing the narrow space within the pelvic cavity. The arms must first be freed before he would be able to draw the head through the funnel-shaped pelvis.

With some difficulty he released the right arm and pulled it down. Then his fingers searched for the left arm. To his consternation he found it caught in the nape of the neck and wedged in the pelvis. He attempted to free the arm by pushing back and rotating the infant. The arm did not budge. Frantically he looked at the clock. Six minutes had passed.

He tried again and again to free the stubborn left arm. The clock ticked on. Eight minutes were gone. Desperation gripped the unfortunate doctor. Here within his grasp was the heir to the Hohenzollerns, and it was suffocating before his eyes.

Grimly he hooked his right index finger in the crotch of the left arm and pulled with all his might. The dull, wooden sound of cracking bone sickened him—and the limp left arm fell out. Now by steady pulling, assisted by the midwife pushing from above, he succeeded at last in bringing forth the head of the infant.

The whole procedure had taken ten minutes. Hurriedly he cut and tied the cord and handed the limp blue baby boy to the midwife who carried it to another table prepared for the care of the newborn.

Pale and exhausted, the doctor staggered over and listened to the infant's heart. It was beating feverishly with scarcely perceptible sounds. But the child was not breathing. The dark blue color of the skin was changing from second to second into the paler hue of death. The midwife started artificial respiration, rhythmically compressing

and releasing the tiny chest. This brought momentarily a pinkish tinge to the baby's skin. But as soon as she stopped it turned blue again. The asphyxiated nerve centers were not yet able to animate the lungs. Every method known to science was used to revive the infant, stimulation of the skin with cold and warm water, swinging the child, but each time the external stimulation was discontinued, the lungs stopped breathing.

The greater part of an hour had passed since the birth. The infant's heart was still beating, not giving up its frantic struggle to live. In the excitement of trying to save the heir to the Prussian throne, the young mother had been almost forgotten. Lying in shock, she was unconscious of everything happening about her and seemed willing to share the fate of her firstborn.

Timidly the second midwife, a young peasant, came forward and suggested a method of resuscitation she had seen used in her village: the oldest and until today the most efficient method—mouth to mouth breathing, blowing the breath of the living into a lifeless body. The desperate doctor consented, and the young peasant girl placed her mouth to the mouth of the princeling and started rhythmically to exhale and inhale. The baby boy's color began to pinken. The legs twitched. After awhile the girl paused. All eyes were fixed on the infant. Then a miracle happened. The baby continued to breathe, filling its lungs with sufficient air to emit the complaining wail of the newborn, the first spontaneous expression of life.

The baby's first cry aroused the young mother from her deathlike slumber. And in another moment the silence of the room was broken by an outburst of joy. Doctors, nurses, and ladies of the Court were crowding around the baby, smiling, laughing, and shaking hands, as the first dim light of the morning of January 27 streaked into the room. No one paid attention to the limp left arm of the baby boy. Weeks passed before the doctors recognized that not only had the bone of the left upper arm been broken, but the nerve trunks had been injured as well. And it was years before the suspicion arose that the brain of the child had been damaged.

The infant born was Prince Wilhelm of Hohenzollern, later Emperor Wilhelm II of Germany.

© 2004 Blackwell Publishing Ltd *Journal of Internal Medicine* 255: 105–112

It is the opinion of the author that the Pavlov school's explanation of nervous processes is totally different from that of Sherrington, and that it constitutes a separate and independent line of inquiry. The author bases all his conceptions of higher nervous activity on the neuromic theory, and though he is aware of much of the newer information concerning the rhythmic electrical activity of the brain, he feels that eventually the Sherrington concept of total nervous activity will adequately encompass the entire problem. It is his purpose in this book to extend the Sherrington theories of the total physiology of the nervous system, and at the same time to elucidate the fallacies of Pavlov. He was a pupil of Pavlov, but has rejected Pavlov's theories as actually incorrect and not adequate even for a working hypothesis in the light of experimental facts. It is the author's opinion "that study of the physiology of higher nervous activity is so complex and difficult that, if anyone formulated a system of working hypotheses which completely accorded with the factual evidence and were not internally contradictory, we should be prepared to accept that system."

JOHN MARTIN

One does not like to write a review by saying the only thing for the reader to do is to read the book for him self but it is almost impossible to point out all the neat facts presented. Alvarez devotes consid-

By Walter C. ...
Paul B. Hoelzer, Jr.

This is not a clinical treatise of the scope of volumes by Bockus, but rather an application of physiology of the gastrointestinal tract to the practice of medicine. It emphasizes fundamental principles and research that may be of the greatest assistance in giving the clinician or research worker an idea such as that which started Banting on the quest for insulin. For, while a great deal of laborious laboratory and clinical work has been done (thus answering the quest for the Holy Grail), the problems have always been well chosen.

The book is extremely important to all doctors because of the wealth of material on gastroenterology collected here. It is of equal help to busy physicians without time to read the entire book because of the adequate summary of information at the end of each chapter. The book is a superb achievement and immensely informative. ARTHUR J. ATKIN

Part 1 contains 180 pages divided into 19 chapters. The first 4 chapters are devoted chiefly to the technique of fluid administration, including the preparation and storage of blood and plasma. The author is much impressed with the sternal route for rapid replacement of blood or plasma when the need arises. Chapter 5 covers the treatment of shock, and Chapter 6 is little with which the reader might take issue. Chapter 7 is devoted to the selection and administration of anesthesia for urgent operations, with particular emphasis on the value of local, spinal, and intravenous methods used alone or in combination. Chapter 8 on "Impending Death under Anesthesia" reviews the methods for the treatment of blue (hypoxic) asphyxia and white (cardiac) asphyxia, with indications and technique for direct cardiac massage.

Chapter 8 on armamentarium, a short enumeration of the general type of instrument required for emergency surgery. This is followed by Chapter 9 which describes the technical details

²FURGER by SUPREMA, Iartian and Pythia
FICS (F-) FACS FICS FICS FICS FICS
more The Williams' Will (Coast)

opening and closing the abdomen by various incisional approaches

Chapter 10 is devoted to the management of post-operative evisceration

Chapter 11 describes the more common lesions which may affect the abdominal wall and extraperitoneal tissues

Chapter 12 is an excellent guide for the inexperienced surgeon regarding the utilization of drainage

Chapter 13 reviews the principles concerned in the treatment of diffuse peritonitis of obscure origin and is followed by 2 chapters on the management of acute appendicitis and its complications. Many will take issue with the incision recommended for drainage of appendiceal abscess placed at right angles to the customary McBurney incision

Chapters 16 and 17 discuss the differentiation and management of acute salpingitis and other conditions simulating acute appendicitis

Chapter 18 describes in detail nonoperative methods for gastric, duodenal and intestinal decompression, and is followed by a short chapter reviewing the indications and technique for establishment of an enterostomy

Part 2 of *Emergency Surgery* contains chapters 20 through 37 and includes 207 pages

Chapters 20 and 21 describe the management of perforated gastric and duodenal ulcers, of bleeding ulcer, and of other causes of hematemesis and melena. Chapter 22 concludes the discussion of the stomach with a short review of acute dilatation, complications of gastric surgery and congenital lesions of the stomach

Chapter 23 is devoted to the common surgical lesions of the gall bladder and bile ducts. The ease with which the author is content to differentiate obstructive from toxic jaundice by the glucose tolerance test might be questioned by many surgeons. The inexperienced reader might benefit from a more detailed evaluation of the proper time for removal of common duct tubes

Chapter 24 on acute pancreatitis makes little reference to the diagnostic value of the amylase or diastase determination, but covers the treatment of this condition in a very satisfactory manner

Chapter 25 discusses the management of such miscellaneous abdominal conditions as subphrenic abscess, pylophlebitis, intraperitoneal rupture of hydatid cyst, and the recognition of abdominal crises of pernicious anemia

Chapter 26 is devoted to the management of patients who have ingested foreign bodies

Chapter 27 describes the treatment of patients with the more common intra-abdominal injuries, including rupture of the spleen or liver, lacerations of the mesentery, injuries to the pancreas, gall bladder, and bile ducts, and rupture of the intestine. This is followed by a chapter on the management of penetrating wounds of the abdomen and abdominothoracic injuries

Chapter 29 describes in detail methods of intestinal resection and anastomosis. It is doubtful whether

the telescoping method for end-to-end anastomosis warrants the enthusiasm afforded it

Chapters 30 through 37 review the common causes of intestinal obstruction in both infants and adults, and their management

These volumes represent an excellent and comprehensive review of the problems of emergency surgery by an exceptionally well qualified author

The reader may be slightly antagonized by the frequent use of the first person and constant reference to the successful accomplishments of the author, however, if one will bear in mind the tremendous experience and established ability of the author, this feature becomes only a minor annoyance. The multitude and excellence of the illustrations leave no questions in the mind of him who seeks advice from these books. The figures average nearly 2 to each page, they are sharp and distinct, and many are in color or tinted. In the opinion of the reviewer, this is a most valuable guide book for the resident surgeon and for those who must perform either emergency or elective surgery without benefit of extensive training or experience. To them, these volumes will give a real helping hand in a time of need

EDWARD W. GIBBS

THE third edition of the *Histopathology of the Peripheral and Central Nervous Systems*¹ has been considerably enlarged and is illustrated by 302 excellent figures, most of them photographs from the author's own collection. The division of the text into the 3 main chapters on diseases of the peripheral nerves, the spinal cord, and the brain is well suited as an aid to the clinical teaching of neurology, though this leads, of necessity, to repetitions when it comes to the description of the different neuropathologic manifestations

The book testifies to the author's encyclopedic knowledge of the neuropathologic literature. One has to appreciate the clarity with which controversial theories are cited and due credit is given to other authors. Of course, the author emphasizes his own theories though they may be opposed to other prevalent present day teaching. One wonders whether it might not have been wiser to accept some of the more modern, well established concepts, e.g. to change the idea that "the Virchow Robin spaces occupy the space between muscularis and adventitia" or that "the choroid plexus of the brain has nothing to do with the production of the cerebrospinal fluid," though others have demonstrated such secretion by injecting fluorescent dyes intravenously and observing them escaping from the choroid plexus of experimental animals

But such minor criticisms should not deter one from acknowledging the value of this textbook which has successfully guided several generations of neurologists in their study of neuropathology. The readers of this journal should be especially interested in the

¹HISTOPATHOLOGY OF THE PERIPHERAL AND CENTRAL NERVOUS SYSTEMS. By George B. Hassin, M.D. 3rd rev. enl. ed. Chicago: The Author, 1948.

chapters on diseases of the muscles and of the peripheral nerves which are well represented

ARTHUR WEIL

THE second edition of *Clinical Urology*¹ by Lowrain E. McCrea, offers a concise kaleidoscopic picture of clinical urology for general practitioners, interns, and medical students. It consists of 503 pages, is well illustrated and the printing is very easy to read.

The author advises against all simultaneous bilateral retrograde pyelograms, but it seems to us there is very little basis for such teaching.

The treatment of sulfonamide anuria is described as excess hydration of the patient. The question of fluid exchange in such conditions is still a moot question. Many excellent clinicians believe these patients

¹CLINICAL UROLOGY. ESSENTIALS OF DIAGNOSIS AND TREATMENT. By Lowrain E. McCrea, M.D. F.A.C.S. F.I.C.S. 2d ed. Philadelphia: I. A. Davis Co., 1948.

are drowned by excessive hydration.

The author should be congratulated for including a very adequate section on gonorrheal urethritis, its complications. It is refreshing to know that there are workers who realize that the genital adenitis must be checked before a gonorrheal urethritis can be pronounced cured.

It is suggested that the section of the book which deals with the so-called neurogenic bladder should include a statement concerning the transurethral resection of the vesical neck in certain of these patients.

A second edition of such a book is very commendable. The progress of medicine makes re-edition mandatory. This is valuable for general practitioners, who have so little time for extra reading. The author initiated this book for the sake of practicality. His original idea has been fulfilled. He has portrayed a simple, straightforward and logical story of urological disease and its treatment.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

DALLAS B. PHEMISTER, Chicago, *President*
FREDERICK A. COLLIER, Ann Arbor, *President-Elect*

PRELIMINARY PROGRAM FOR THE 35th CLINICAL
CONGRESS—THE STEVENS, CHICAGO,
OCTOBER 17 TO 21, 1949

TELEVISED operations in color will be one of the new features of the thirty-fifth Clinical Congress of the American College of Surgeons and the Sixth Inter-American Congress of Surgery which will be held from October 17 through 23 with headquarters at The Stevens in Chicago. The Inter-American Congress will meet concurrently with the Clinical Congress from October 17 to 21 and will continue in session two days longer. Many delegates and other surgeons from Latin-American countries are registering, along with their colleagues from the United States and Canada, with the anticipation of a seven-day surgical program of extremely great interest. More than the usual number of guests from other continents are also expected as a result of the holding of the thirteenth Congress of the International Society of Surgery in New Orleans the week preceding the two Chicago Congresses, many of the delegates to that meeting are planning to remain in this country to attend the Clinical Congress.

Every Fellow of the American College of Surgeons is a member of the Association of Inter-American Congresses of Surgery by virtue of the fact that the College is a signatory member of that organization. Its scientific and social sessions on Saturday and Sunday are therefore open to all Fellows. The members of the other signatory societies of the Association are likewise entitled to attend the Clinical Congress clinics and scientific meetings, since it is the practice for the host country to make a joint event of its own annual surgical Congress and that of the Inter-American group.

In making hotel reservations it is therefore well to bear in mind the seven-day extent of the Congresses. The program of the separate sessions of the Inter-American Congress is quite different in

nature from that of the Clinical Congress and will offer an unusual opportunity to hear important surgical themes discussed from the standpoint of similarities and differences in methods of treatment in a number of countries. The Inter-American Congress of Surgery will undoubtedly enhance the international prestige of the American College of Surgeons and will familiarize North American Fellows and overseas guests with surgical progress in the other Americas.

Preliminary plans for the program of the Sixth Inter-American Congress of Surgery are described in a separate article which follows. The opening or inaugural session will be held on Friday morning, October 21. This session is for delegates and special guests only. The scientific sessions on Saturday and Sunday, and the official banquet on Saturday evening, will be open to all Fellows, whose presence will help to show how deeply interested the American College of Surgeons is in the cultivation of mutually beneficial professional and social relationships among surgeons out the Americas.

CLINICAL CONGRESS PROGRAM

A general assembly for both surgeons and hospital personnel on Monday morning, October 17, will be the opening session of the varied and comprehensive program of meetings which will be held at the headquarters hotel and nearby auditoriums. Scientific sessions, official meetings, hospital conferences, showings of medical motion pictures, telecasts, and exhibits will follow during the five days of the Clinical Congress. The special sessions of the Sixth Inter-American Congress of Surgery on Friday, Saturday, and Sunday, will, according to present plans, be held in the John B. Murphy Auditorium of the College. All registrants for both Congresses will be interested in the ex-

chapters on diseases of the muscles and of the peripheral nerves which are well represented

ARTHUR WEIL

THE second edition of *Clinical Urology*¹ by Lowrain E McCrea, offers a concise kaleidoscopic picture of clinical urology for general practitioners, interns, and medical students. It consists of 503 pages, is well illustrated and the printing is very easy to read.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

DALLAS B PHEMISTER, Chicago, *President*
FREDERICK A COLLER, Ann Arbor, *President-Elect*

PRELIMINARY PROGRAM FOR THE 35th CLINICAL CONGRESS—THE STEVENS, CHICAGO, OCTOBER 17 TO 21, 1949

TELEvised operations in color will be one of the new features of the thirty-fifth Clinical Congress of the American College of Surgeons and the Sixth Inter-American Congress of Surgery which will be held from October 17 through 23 with headquarters at The Stevens in Chicago. The Inter-American Congress will meet concurrently with the Clinical Congress from October 17 to 21 and will continue in session two days longer. Many delegates and other surgeons from Latin-American countries are registering, along with their colleagues from the United States and Canada, with the anticipation of a seven-day surgical program of extremely great interest. More than the usual number of guests from other continents are also expected as a result of the holding of the thirteenth Congress of the International Society of Surgery in New Orleans the week preceding the two Chicago Congresses, many of the delegates to that meeting are planning to remain in this country to attend the Clinical Congress.

Every Fellow of the American College of Surgeons is a member of the Association of Inter-American Congresses of Surgery by virtue of the fact that the College is a signatory member of that organization. Its scientific and social sessions on Saturday and Sunday are therefore open to all Fellows. The members of the other signatory societies of the Association are likewise entitled to attend the Clinical Congress clinics and scientific meetings, since it is the practice for the host country to make a joint event of its own annual surgical Congress and that of the Inter-American group.

In making hotel reservations it is therefore well to bear in mind the seven-day extent of the Congresses. The program of the separate sessions of the Inter-American Congress is quite different in

nature from that of the Clinical Congress and will offer an unusual opportunity to hear important surgical themes discussed from the standpoint of similarities and differences in methods of treatment in a number of countries. The Inter-American Congress of Surgery will undoubtedly enhance the international prestige of the American College of Surgeons and will familiarize North American Fellows and overseas guests with surgical progress in the other Americas.

Preliminary plans for the program of the Sixth Inter-American Congress of Surgery are described in a separate article which follows. The opening or inaugural session will be held on Friday morning, October 21. This session is for delegates and special guests only. The scientific sessions on Saturday and Sunday, and the official banquet on Saturday evening, will be open to all Fellows, whose presence will help to show how deeply interested the American College of Surgeons is in the cultivation of mutually beneficial professional and social relationships among surgeons throughout the Americas.

CLINICAL CONGRESS PROGRAM

A general assembly for both surgeons and hospital personnel on Monday morning, October 17, will be the opening session of the varied and comprehensive program of meetings which will be held at the headquarters hotel and nearby auditoriums. Scientific sessions, official meetings, hospital conferences, showings of medical motion pictures, telecasts, and exhibits will follow during the five days of the Clinical Congress. The special sessions of the Sixth Inter-American Congress of Surgery on Friday, Saturday, and Sunday, will, according to present plans, be held in the John B. Murphy Auditorium of the College. All registrants for both Congresses will be interested in the ex-

tensive display of technical and scientific exhibits in the exhibition hall on the lower level of the headquarters hotel

CLINICS

Operative and nonoperative clinics will be held in some twenty hospitals in the Chicago area each day during the Clinical Congress. The hospitals which will participate in the clinical program, and which are listed later in this article, are approved by the American College of Surgeons for graduate training in surgery. The schedule of clinics, which will cover general surgery, obstetrics and gynecology, fractures and other traumas, orthopedic surgery, thoracic surgery, plastic surgery, neurosurgery, genitourinary surgery, and ophthalmology and otorhinolaryngology, will be published in a *Daily Clinical Bulletin* which will be issued each day during the Clinical Congress. The clinic schedules will also be posted on bulletin boards.

TELEVISION

Operations will be telecast, in color, to the hotel from St. Luke's Hospital at scheduled periods each day. The television program will be over a closed circuit, impossible to pick up on public sets. The operations and demonstrations will be transmitted to about twenty color transmission receivers in the hotel. The engineers anticipate excellent reception since the hospital is in a direct line of vision from the roof of The Stevens. The television will be sponsored by Smith, Kline & French Laboratories.

The successful demonstrations of television at the Clinical Congress in New York in 1947, and at the Clinical Congress in Los Angeles in 1948, make it highly desirable to continue the use of this medium. Even when limited to black and white images, as it was then, the surgeons were most enthusiastic. Color, demonstrated in televised surgery telecasts for the first time at the American Medical Association's convention in Atlantic City in June, greatly enhances the value of the telecasts.

Television has proved to be an ideal means of furthering the "Show me" purpose which was the main incentive for the founding of the Clinical Congress of Surgeons of North America in 1910, three years before the American College of Surgeons was organized. That first Clinical Congress was held in Chicago. The 1949 meeting will be the ninth held in that city.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening, October 17. The complete program

appears on another page. At this meeting the officers-elect, consisting of Dr. Frederick A. Collier, of Ann Arbor, president, Dr. Donald G. Tollefson, of Los Angeles, first vice-president, and Dr. Robert M. Moore, of Galveston, second vice-president, will be installed. The outgoing president, Dr. Dallas B. Phemister, of Chicago, will preside and will deliver the Presidential Address. His subject will be, "An Evaluation of Full-time and Group Practice for the Clinical Faculty of a Medical School."

Sir James R. Learmonth, of Edinburgh, will deliver the fourth Martin Memorial Lecture. His subject will be "Collateral Circulations, Natural and Artificial."

CONVOCATION

The formal initiation ceremonies for the new Fellows will be a colorful feature of the annual Convocation which will be held on the final evening, Friday, October 21. Honorary fellowships will also be conferred on this occasion. Lord Webb-Johnson, of London, president of the Royal College of Surgeons of England, will deliver the Fellowship Address. His subject will be "Science in Surgery—Stop, and Look, and Listen."

GENERAL SURGERY

In general surgery, the program at the headquarters hotel will embrace three evening symposia and six afternoon panel discussions.

The subjects for the symposia on Tuesday, Wednesday, and Thursday evenings, respectively, will be "Acute Surgical Emergencies in Gynecology and Obstetrics", "Blood Coagulation and the Use of Anticoagulants", and "Malignant Disease." At the Wednesday evening session there will also be presented the Fracture Oration by Dr. Otto J. Hermann, of Boston, on the subject "Fracture Hazards."

The following subjects have been chosen for the afternoon panel discussions in general surgery, the first one of which will be held from 1:30 to 3:00 and the second from 3:30 to 5:00 o'clock on Monday, Tuesday, and Wednesday: "Surgical Lesions of the Breast", "Fractures of the Skull", "Massive Upper Abdominal Hemorrhage", "New Surgical Technics in Drug Treated Infections", "The Management of Acute Emergencies Occurring during Operations", and "Preoperative and Postoperative Care and Anesthesia for Infants."

Detailed programs appear on succeeding pages.

SURGICAL SPECIALTIES

Panel discussions for the surgical specialties will be held on Friday afternoon from 1:30 to 4:45.

o'clock. The panels will be held concurrently in the following fields: orthopedic surgery, plastic surgery, urology, thoracic surgery, neurological surgery, and obstetrics and gynecology. Programs are shown on succeeding pages.

OPHTHALMOLOGY AND OTOLARYNGOLOGY

Separate programs for specialists in ophthalmology and otolaryngology are being planned, the details of which will be announced later. Operative clinics in these specialties in the hospitals will also be particularly emphasized this year.

SYMPOSIA ON AMPUTEES AND ON TRAUMA

A symposium on "The Care and Education of Amputees" will be held on Tuesday morning from 10 00 a m until noon. On Tuesday afternoon from 2 00 until 5 00 o'clock, a symposium on trauma will be held at which the following subjects will be discussed: "Plastic Surgical Repair of Radiation Injuries", "Observations on Results of Shoulder Cuff Repair", "Use of Intramedullary Fixation in Fractures", "A Prolonged End Result Study of 335 Intracapsular Fractures of the Femoral Neck", "An Analysis of the Management and Complications of Multiple (3 or more) Rib Fractures", "Blood and Blood Substitutes in Trauma", "Fractures of the Tarsal and Metatarsal Bones", and "Reconstructive Surgery Following Trauma." Dr. Robert H. Kennedy, of New York, chairman of the Committee on Trauma, will preside at both sessions. The programs appear on succeeding pages.

SYMPOSIUM ON CANCER

A symposium on cancer will be held on Wednesday afternoon from 2 00 until 5 00 o'clock, with Dr. Grantley W. Taylor, of Boston, chairman of the Cancer Committee, presiding. The program appears on a succeeding page.

HOSPITAL CONFERENCES

The twenty-eighth Hospital Standardization Conference will be held during the first 4 days of the Clinical Congress. Its opening meeting will constitute the first formal session of the Clinical Congress and will be for both surgeons and hospital representatives. Dr. Dallas B. Phemister, president of the College, will preside.

Hospital administrators, trustees, members of medical staffs, nurses, technicians, dietitians, and heads of the various hospital departments and their personnel, are invited to participate in the discussions at the hospital conferences which will be directed by leading authorities in the hospital

field in the United States and Canada. The program will include formal sessions, panel discussions, round table conferences, symposia, and forums. An outline of the program appears on a succeeding page.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems, one of the most popular features of Clinical Congresses during the past few years, will be held on Monday through Thursday afternoons, and Tuesday through Friday mornings. Two concurrent sessions will be held on Wednesday morning only. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented under the general direction of Dr. Owen H. Wangenstein, chairman of the committee, Forum on Fundamental Surgical Problems. An outline of the main topics follows: Monday, 2 00—5 00 p m —Gall Bladder and Pancreas, Urology, Orthopedics, Plastic Surgery.

Tuesday, 9 00—12 00 a m —Surgery of the Heart

Tuesday, 2 00—5 00 p m —Vascular Surgery and Surgery of Hypertension

Wednesday, 9 00—12 00 a m —Neurosurgery

Wednesday, 9 00—12 00 a m —Thyroid, Lungs, Esophagus, Anesthesia

Wednesday, 2 00—5 00 p m —Stomach and Intestines

Thursday, 9 00—12 00 a m —Wounds and Wound Healing, Burns, Infections, Shock

Friday, 9 00—12 00 a m —Blood and Body Fluids, Portacaval Anastomosis, Cancer

The Thursday afternoon session, from 1 00 to 3 30, will be conducted as a seminar, with Dr. I. S. Ravdin as moderator, on the subject "Nutritional Problems including a Consideration of the Use of Fluids and Electrolytes."

ASSEMBLY OF INITIATES

The 1949 initiates will attend an assembly on Friday afternoon from 1 45 to 2 30 o'clock. Dr. Frederick A. Collier, newly installed president of the College, will preside. Dr. Irvin Abell, chairman of the Board of Regents, and Dr. Bowman C. Crowell, Dr. Malcolm T. MacEachern, and Dr. H. Prather Saunders, associate directors, will present briefly an outline of the program of the College.

OTHER OFFICIAL MEETINGS

The annual meeting of the Governors and Fellows of the College will be held on Thursday afternoon at 3 30 o'clock. Reports on activities

tensive display of technical and scientific exhibits in the exhibition hall on the lower level of the headquarters hotel

CLINICS

Operative and nonoperative clinics will be held in some twenty hospitals in the Chicago area each day during the Clinical Congress. The hospitals which will participate in the clinical program, and which are listed later in this article, are approved by the American College of Surgeons for graduate training in surgery. The schedule of clinics, which will cover general surgery, obstetrics and gynecology, fractures and other traumas, orthopedic surgery, thoracic surgery, plastic surgery, neurosurgery, genitourinary surgery, and ophthalmology and otorhinolaryngology, will be published in a *Daily Clinical Bulletin* which will be issued each day during the Clinical Congress. The clinic schedules will also be posted on bulletin boards.

TELEVISION

Operations will be telecast, in color, to the hotel from St. Luke's Hospital at scheduled periods each day. The television program will be over a closed circuit, impossible to pick up on public sets. The operations and demonstrations will be transmitted to about twenty color transmission receivers in the hotel. The engineers anticipate excellent reception since the hospital is in a direct line of vision from the roof of The Stevens. The television will be sponsored by Smith, Kline & French Laboratories.

The successful demonstrations of television at the Clinical Congress in New York in 1947, and at the Clinical Congress in Los Angeles in 1948, make it highly desirable to continue the use of this medium. Even when limited to black and white images, as it was then, the surgeons were most enthusiastic. Color, demonstrated in televised surgery telecasts for the first time at the American Medical Association's convention in Atlantic City in June, greatly enhances the value of the telecasts.

Television has proved to be an ideal means of furthering the "Show me" purpose which was the main incentive for the founding of the Clinical Congress of Surgeons of North America in 1910, three years before the American College of Surgeons was organized. That first Clinical Congress was held in Chicago. The 1949 meeting will be the ninth held in that city.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening, October 17. The complete program

appears on another page. At this meeting the officers-elect, consisting of Dr. Frederick A. Collier, of Ann Arbor, president, Dr. Donald G. Tollefson, of Los Angeles, first vice-president, and Dr. Robert M. Moore, of Galveston, second vice-president, will be installed. The outgoing president, Dr. Dallas B. Phemister, of Chicago, will preside and will deliver the Presidential Address. His subject will be, "An Evaluation of Full-time and Group Practice for the Clinical Faculty of a Medical School."

Sir James R. Learmonth, of Edinburgh, will deliver the fourth Martin Memorial Lecture. His subject will be "Collateral Circulations, Natural and Artificial."

CONVOCATION

The formal initiation ceremonies for the new Fellows will be a colorful feature of the annual Convocation which will be held on the final evening, Friday, October 21. Honorary fellowships will also be conferred on this occasion. Lord Webb-Johnson, of London, president of the Royal College of Surgeons of England, will deliver the Fellowship Address. His subject will be "Science in Surgery—Stop, and Look, and Listen."

GENERAL SURGERY

In general surgery, the program at the headquarters hotel will embrace three evening symposia and six afternoon panel discussions.

The subjects for the symposia on Tuesday, Wednesday, and Thursday evenings, respectively, will be "Acute Surgical Emergencies in Gynecology and Obstetrics", "Blood Coagulation and the Use of Anticoagulants", and "Malignant Disease." At the Wednesday evening session there will also be presented the Fracture Oration by Dr. Otto J. Hermann, of Boston, on the subject "Fracture Hazards."

The following subjects have been chosen for the afternoon panel discussions in general surgery, the first one of which will be held from 1:30 to 3:00 and the second from 3:30 to 5:00 o'clock on Monday, Tuesday, and Wednesday: "Surgical Lesions of the Breast", "Fractures of the Skull", "Massive Upper Abdominal Hemorrhage", "New Surgical Techniques in Drug Treated Infections", "The Management of Acute Emergencies Occurring during Operations", and "Preoperative and Postoperative Care and Anesthesia for Infants."

Detailed programs appear on succeeding pages.

SURGICAL SPECIALTIES

Panel discussions for the surgical specialties will be held on Friday afternoon from 1:30 to 4:45.

The Advisory Committee on Programs consists of Dr George H Miller, chairman, and Doctors Warren H Cole, Sumner L Koch, Michael L Mason, Charles B Puestow, Bowman C Crowell, H Prather Saunders, Charles F Branch, and Malcolm T MacEachern

MEDICAL MOTION PICTURES

The showing of medical motion pictures each day will again be a popular feature of the Clinical Congress. The latest available films on surgery and related subjects will be presented. Special showings will be arranged of medical motion pictures in the fields of ophthalmology and otorhinolaryngology. Both sound and silent films will be shown, all of which will have been approved by the Committee on Motion Pictures.

Some of the newer medical motion pictures which have been or are being produced under Directing Committees of the College, will be presented during the Clinical Congress. Among these will be the film entitled "Injuries of the Peripheral Nerves" directed by Dr Loyal Davis, under a grant from the Johnson & Johnson Research Foundation. A premiere showing of this particular film will take place in the Murphy Memorial Auditorium of the College at the time of the Congress in October.

TECHNICAL AND EDUCATIONAL EXHIBITION

The Technical and Educational Exhibits will be held in the Exhibition Hall on the lower level of The Stevens. There will be represented leading manufacturers of surgical instruments, of x-ray apparatus, of sterilizers, of operating room lights, of ligatures, of dressings, of hospital apparatus and supplies of all kinds, and of pharmaceuticals, and publishers of medical books.

There will also be presented exhibits depicting the work of the College.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Advance registration will greatly expedite the procedure of registering. No registration fee will be charged. Fellows whose dues are paid to December 31, 1948. For endorsed Junior and Senior Candidates, the fee will be \$5.00. Non-Fellows who after individual consideration are permitted to register, will pay a fee of \$10.00. No registration fee will be required of initiates of the class of 1949.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible. In making these, communica-

tions should be addressed to the Convention Housing Bureau, 105 West Madison Street, Chicago, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations, both for surgeons and hospital representatives, are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was recently sent to Fellows.

A list of the principal participating hotels and minimum rates follows:

Chicago Hotels	Single	Double
Atlantic	\$3.50	\$5.00
Bismarck	5.00	8.00
Brevoort	3.50	6.00
Chicagoan	3.75	5.50
Drake	4.50	7.50
Eastgate	3.50	5.50
Hamilton	4.00	6.00
Harrison	3.00	4.00
Knickerbocker	5.00	8.00
Maryland	4.00	6.00
Midland	3.00	4.50
Palmer House	4.00	8.00
Sheraton	3.85	6.40
Stevens	4.50	7.00

PRELIMINARY PROGRAM

PRESIDENTIAL MEETING

Monday, 8 15-10 30 p m — Ballroom, The Stevens
DALLAS B. PHEMISTER, M.D., F.A.C.S., Chicago, president, American College of Surgeons, presiding.

Processional—Officers, Regents, and Distinguished Guests

Invocation

Address of Welcome WARREN H. COLE, M.D., F.A.C.S., Chicago, chairman, Committee on Arrangements

Introduction of Distinguished Guests ARTHUR W. ALLEN, M.D., F.A.C.S., Boston, vice chairman, Board of Regents

Address of the Retiring President. An Evaluation of Full-time and Group Practice for the Clinical Faculty of a Medical School. DALLAS B. PHEMISTER, M.D.

Inauguration of Officers

Presented by HOWARD A. PATTERSON, M.D., F.A.C.S., retiring first vice president

First vice president DONALD G. TOLLEFSON, M.D., F.A.C.S., Los Angeles

Second vice president ROBERT M. MOORE, M.D., F.A.C.S., Galveston

President FREDERICK A. COLLIER, M.D., F.A.C.S., Ann Arbor

The Fourth Martin Memorial Lecture. Collateral Circulations, Natural and Artificial

of the American College of Surgeons, of great interest to all of its Fellows, will be presented by officers, chairmen, and administrative staff members, following the election of officers

Four important committee meetings will be held on Wednesday as follows: State and Provincial Executive Committees, 10 00 to 11 00 a m, State and Provincial Credentials Committees and Committees on Applicants and Judiciary Committees, 11 00 a m to 12 00 noon, the Committee on Trauma and Regional Committees (formerly the Committee on Fractures and Other Traumas), 3 30 to 5 30 p m, and the annual dinner and meeting of the Cancer Committee, 6 30 p m

Thursday committee meetings will include a meeting of the Committee on the Library and the annual dinner meeting of the Committee on Trauma

COMMITTEE ON ARRANGEMENTS AND EXECUTIVE COMMITTEE

The Chicago Committee on Arrangements and the Executive Committee for the Clinical Congress are actively at work on arrangements for the program. The membership of these committees follows

Committee on Arrangements

Warren H. Cole, M D, F A C S, chairman
Lester R. Dragstedt, M D, F A C S, vice chairman
Michael L. Mason, M D, F A C S, secretary
Dallas B. Phemister, M D, F A C S, president and regent of the College
William C. Adams, M D, F A C S
James J. Callahan, M D, F A C S
Fremont A. Chandler, M D, F A C S
Edward A. Christofferson, M D, F A C S
Vernon C. David, M D, F A C S
Loyal Davis, M D, F A C S
M. Edward Davis, M D, F A C S
Paul W. Greeley, M D, F A C S
Paul H. Holinger, M D, F A C S
Sumner L. Koch, M D, F A C S
Herman L. Kretschmer, M D, F A C S
Walter G. Maddock, M D, F A C S
Foster L. McMillan, M D, F A C S
Karl A. Meyer, M D, F A C S
Harry A. Oberhelman, M D, F A C S
Willis J. Potts, M D, F A C S
Charles B. Puestow, M D, F A C S
Herbert E. Schmitz, M D, F A C S
Derrick T. Vail, M D, F A C S

Executive Committee

Warren H. Cole, M D, chairman
Lester R. Dragstedt, M D, vice chairman
Michael L. Mason, M D, secretary
Dallas B. Phemister, M D, president and regent of the College
James J. Callahan, M D
Loyal Davis, M D
Walter G. Maddock, M D

PARTICIPATING HOSPITALS AND HOSPITAL CLINICS COMMITTEE

Augustana Hospital OSCAR E. NADEAU, M D, F A C S
Children's Memorial Hospital PAUL F. FOX, M D, F A C S
Cook County Hospital MANUEL E. LICHTENSTEIN, M D, F A C S

President FREDERICK A. COLLIER, M.D., F.A.C.S., Ann Arbor

The Fourth Martin Memorial Lecture. Colateral Circulations, Natural and Artificial

SIR JAMES R. LEARMONTH, M B, Ch M,
F R C S (Ed), Edinburgh, Scotland

Recessional

CONVOCATION

Friday, 8 15-10 30 p m—Ballroom, The Stevens

FREDERICK A. COLLIER, M D, F A C S, Ann Arbor, President, American College of Surgeons, Presiding

Processional—Initiates, Officers, Regents, and Distinguished Guests

Invocation

Presentation of Initiates for Fellowship IRVIN ABELL, M D, F A C S, Louisville, Chairman, Board of Regents

Fellowship Pledge Recital by Initiates

Conferring of Fellowships by the President FREDERICK A. COLLIER, M D

Conferring of Honorary Fellowships The President

Fellowship Address Science in Surgery—Stop, and Look, and Listen LORD WEBB-JOHNSON, K. C V O, C B E, D S O, T D, F A C S (Hon), London

Recessional

EVENING SCIENTIFIC SESSIONS

Tuesday, 8 00—10 30 p m

Symposium on Acute Surgical Emergencies in Gynecology and Obstetrics—

General Introduction NEWELL W. PHILPOTT, M D, F A C S, Montreal

Tubal Pregnancy, Its Diagnosis and Treatment LEWIS C. SCHEFFEY, M D, F A C S, Philadelphia

Pelvic Peritonitis Occurring in the Obstetrical or Gynecological Patient FRANK GLENN, M D, F A C S, New York

Emergency Cesarean Section WILLIAM E. STUDDIFORD, M D, F A C S, New York

Wednesday, 8 00—10 30 p m

Fracture Oration Fracture Hazards OTTO J. HERMANN, M D, F A C S, Boston

Symposium on Blood Coagulation and the Use of Anticoagulants—

The Significance of Different Methods for Prothrombin Estimation and Their Relative Values JOHN H. OLWIN, M D, F A C S, Chicago

Studies on Antithrombin and Etiologic Factors in Phlebothrombosis JOHN H. KAY, M D, New Orleans

A Further Report on Dicumarol Prophylaxis Against Venous Thrombosis in Women

GEORGE VAN S. SMITH, M D, F A C S,
Brookline, Massachusetts

Thursday, 8 00—10 30 p m

Symposium on Malignant Disease—

Chemotherapy in Malignant Neoplastic Disease CARL V. MOORE, M D, St Louis

Hormone Therapy of Cancer CHARLES B. HUGGINS, M D, Chicago

What We Have Learned from Isotopes Concerning Depletion and Repair in Surgical Patients FRANCIS D. MOORE, M D, F A C S, Boston

The Use of Radioactive Iodine in Studying the Pathologic Physiology of Thyroid Cancer RULON W. RAWSON, M D, New York

PANEL DISCUSSIONS

GENERAL SURGERY

Monday, 1 30—3 00 p m

Surgical Lesions of the Breast—

Moderator GEORGE G. FINNEY, M D, F A C S, Baltimore

Collaborators J. MONTGOMERY DEEVER, M D, F A C S, Philadelphia, STUART W. HARRINGTON, M D, F A C S, Rochester, Minnesota, W. PERRIN NICOLSON, M D, Atlanta, HUGH H. TROUT, M D, F A C S, Roanoke

Monday, 3 30—5 00 p m

Fractures of the Skull—

Moderator ELDRIDGE H. CAMPBELL, M D, F A C S, Albany

Collaborators FRANK H. MAYFIELD, M D, F A C S, Cincinnati, DONALD MUNRO, M D, F A C S, Boston, HARRY B. WILKINS, M D, F A C S, Oklahoma City

Tuesday, 1 30—3 00 p m

Massive Upper Abdominal Hemorrhage—

Moderator JOHN H. MULHOLLAND, M D, F A C S, New York

Collaborators ROBERT ELMAN, M D, F A C S, St Louis, CHARLES G. JOHNSTON, M D, F A C S, Detroit, JOHN D. STEWART, M D, F A C S, Buffalo

Tuesday, 3 30—5 00 p m

New Surgical Technics in Drug Treated Infections—

Moderator CHAMP LYONS, M D, New Orleans

Collaborators HARVEY S. ALLEN, M D, F A C S, Chicago, FRANK B. BERRY, M D,

F A C S , New York, GEORGE K CARPENTER, M D , F A C S , Nashville

Wednesday, 1 30—3 00 p m

The Management of Acute Emergencies Occurring During Operations—

Moderator I MIMS GAGE, M D , F A C S , New Orleans

Collaborators BENTLEY P COLCOCK, M D , F A C S , Boston, DANIEL C ELKIN, M D , F A C S , Atlanta, NORMAN E FREEMAN, M D , F A C S , San Francisco, CARL A MOYER, M D , F A C S , Dallas

Wednesday, 3 30—5 00 p m

Preoperative and Postoperative Care and Anesthesia for Infants—

Moderator THOMAS H LANMAN, M D , F A C S , Boston

Collaborators C EVERETT KOOP, M D , Philadelphia, WILLIS J POTTS, M D , F A C S , Chicago, ROBERT M SMITH, M D , Boston

SYMPOSIUM ON AMPUTEES

Tuesday, 10 00 a m —12 00 noon

ROBERT H KENNEDY, M D , F A C S , New York, chairman, Committee on Trauma, Presiding

The Care and Education of Amputees RUFUS H ALLDREDGE, M D , F A C S , New Orleans, HENRY H KESSLER, M D , F A C S , Newark, and LEONARD T PETERSON, M D , F A C S , Washington, D C

SYMPOSIUM ON TRAUMA

Tuesday, 2 00—5 00 p m

ROBERT H KENNEDY, M D , F A C S , New York, chairman, Committee on Trauma, Presiding

Plastic Surgical Repair of Radiation Injuries JAMES BARRETT BROWN, M D , F A C S , St Louis

Observations on Results of Shoulder Cuff Repair HARRISON L McLAUGHLIN, M D , F A C S , New York

Use of Intramedullary Fixation in Fractures HAROLD A SOFIELD, M D , F A C S , Chicago

A Prolonged End-Result Study of 235 Intracapsular Fractures of the Femoral Neck MATHER CLEVELAND, M D , F A C S , New York

An Analysis of the Management and Complications of Multiple (3 or more) Rib Fractures DUNCAN A CAMERON, M D , Detroit

Blood and Blood Substitutes in Trauma JONATHAN E RHOADS, M D , F A C S , Philadelphia

Fractures of the Tarsal and Metatarsal Bones FRANCIS M MCKEEVER, M D , F A C S , Los Angeles

Reconstructive Surgery Following Trauma TRUMAN G BLOCKER, JR , M D , F A C S

SYMPOSIUM ON CANCER

Wednesday, 2 00—5 00 p m

GRANTLEY W TAYLOR, M D , F A C S , Boston, chairman, Cancer Committee, American College of Surgeons, Presiding

Melano-epitheliomas HAMILTON MONTGOMERY, M D , Rochester, Minnesota

Benign Bone Tumors MURRAY M COPELAND, M D , F A C S , Washington, D C

Branchiogenic Cancer HAYES MARTIN, M D , F A C S , New York

What Is a Precancerous Lesion? FRED W STEWART, M D , New York

Cancer of the Kidney HERMAN L KRETSCHMER, M D , F A C S , Chicago

Sarcomas of the Soft Parts ARTHUR PURDY STOUT, M D , New York

SURGICAL SPECIALTIES

PANEL DISCUSSIONS

Friday, 1 30—4 45 p m

ORTHOPEDIC SURGERY

Moderator GUY A CALDWELL, M D , F A C S , New Orleans

Management of Established Non-Union of the Long Bones

Collaborators HUGH SMITH, M D , F A C S , Memphis, FRANK E STINCHFIELD, M D , F A C S , New York, ALEJANDRO VELASCO ZIMBRON, M D , Mexico City

Indications and Technic for Arthrodeses of the Joints of the Foot and Ankle in Post-Traumatic Conditions

Collaborators HAROLD B BOYD, M D , F A C S , Memphis, JAMES A DICKSON, M D , F A C S , Cleveland, C LESLIE MITCHELL, M D , F A C S , Detroit

PLASTIC SURGERY

Moderator JEROME P WEBSTER, M D , F A C S , New York

Plastic Surgery and the Treatment of Malignant Skin Disease

Collaborators JAMES BARRETT BROWN, M D, F A C S, St Louis, W BRANDON MACOMBER, M D, F A C S, Albany, CLAIRE L STRAITH, M D, F A C S, Detroit

The Use of Skin Homografts

Collaborators JAMES F CONNELL, M D, Fort Sam Houston, WILLIAM P LONGMIRE, JR, M D, Los Angeles, BLAIR O ROGERS, M D, Minneapolis

UROLOGY

Moderator GEORGE F CAHILL, M D, F A C S, New York

Hydronephrosis Due to Upper Ureter Obstruction

Collaborators GRAYSON L CARROLL, M D, F A C S, St Louis, FRED E B FOLEY, M D, St Paul, PARKER G SMITH, M D, F A C S, Cincinnati

Ureteral Intestinal Transplantation

Collaborators CHARLES C HIGGINS, M D, F A C S, Cleveland, VICTOR F MARSHALL, M D, F A C S, New York, JAMES T PRIESTLY, M D, F A C S, Rochester

THORACIC SURGERY

Moderator BRIAN B BLADES, M D, F A C S, Washington

Surgery of the Heart and Great Vessels

Collaborators ALFRED BLALOCK, M D, F A C S, Baltimore, THOMAS H BURFORD, M D, F A C S, St Louis, EDWARD M KENT, M D, Pittsburgh

Intrathoracic Tumors

Collaborators (Same as above)

NEUROLOGICAL SURGERY

Moderator ALFRED W ADSON, M D, F A C S, Rochester, Minnesota

Chemical and Physical Diagnostic Aids in the Localization of Brain Tumors

Collaborators GEORGE MOORE, M D, Minneapolis, ERIC OLDBERG, M D, F A C S, Chicago, BERTRAM SELVERSTONE, M D, Boston, HENDRICK J SVIEN, M D, Rochester, WILLIAM H SWEET, M D, Boston

Diagnosis and the Localization of Intraspinal Tumors

Collaborators PAUL C BUCY, M D, F A C S, Chicago, T C ERICKSON, M D, Madison, HAROLD C VORIS, M D, F A C S, Chicago

OBSTETRICS AND GYNECOLOGY

Moderator FRANKLIN L PAYNE, M D, F A C S, Philadelphia

Carcinoma of the Uterine Cervix—Modern Concepts in Diagnosis and Treatment

Collaborators ROBERT GORDON DOUGLAS, M D, New York, HERBERT F TRAUT, M D, F A C S, San Francisco, PAUL A YOUNGE, M D, Brookline

Cesarean Section—Should the Latitude of Its Indications be Broadened

Collaborators D ANTHONY D'ESOPPO, M D, New York, CARL P HUBER, M D, Indianapolis, H HUDNALL WARE, JR, M D, F A C S, Richmond

TWENTY-EIGHTH ANNUAL HOSPITAL STANDARDIZATION CONFERENCE

Monday, 10 00 a m -12 30 p m

GENERAL ASSEMBLY

DALLAS B PREMISTER, M D, F A C S, Chicago, president, American College of Surgeons, Presiding

The Ever Present Challenge—Good Care of the Patient IRVIN ABELL, M D, F A C S, Chicago, chairman, Board of Regents, American College of Surgeons

The Health of the Nation—Our Greatest Asset HARRISON RAY ANDERSEN, D D, Chicago, Pastor, Fourth Presbyterian Church

The Voluntary Hospital—The Foundation of the Present Hospital System REV JOHN W BARRETT, Chicago, director of Catholic Hospitals, Archdiocese of Chicago, president, Catholic Hospital Association

Trends in Legislation Affecting Hospitals GEORGE BUGBEE, Chicago, executive director, American Hospital Association

Monday, 2 00-5 00 p m

Panel Discussion—Standards of Professional Services for the Good Care of the Patient as Rendered by

The Radiologist, the Pathologist, the Anesthesiologist, the Physical Therapist

Tuesday, 10 00 a m -12 30 p m

Standards for the Institutional Care of Psychiatric Patients in (a) Mental Hospitals, (b) General Hospitals, Tuberculous Patients in (a) Sanatoria, (b) General Hospitals

Tuesday, 2 00-5 00 p m

Seminar and Round Table Conference
Discussion of Standards for Hospitals

Tuesday, 7 30-10 00 p m

Special Collaborative Conference for Doctors, Hospital Trustees and Administrators

Theme Understanding and Cooperation from the standpoint of the Doctor, the Trustee, and the Administrator

Wednesday, 8 00-9 30 a m

Breakfast Conference on Public Relations—Joint Session for Press and Radio Representatives and Hospital and Medical Personnel

Wednesday, 10 00 a m -12 30 p m

Theme—Hospital Costs and Maintenance of Standards

Present and Future Trends in Hospital Costs, Financial Responsibility for the Indigent, Blue Cross and Blue Shield Plans as Factors in Relieving the Hospital's Financial Burden

Wednesday, 2 00-5 00 p m

Theme—The Medical Staff of the Hospital Basic Considerations in Organization, Duties and Responsibilities

Essentials of Adequate Medical Staff Organization, Control of the Professional Work, Review and Analysis of the Clinical Work

Wednesday, 8 00-10 00 p m

Discussion Conference with the Field Staff of the American College of Surgeons on the Activities of the College as they Affect Hospitals

Hospital Standardization and Point Rating, Graduate Training in Surgery, Medical Service in Industry, Library and Department of Literary Research, Medical Motion Pictures, Sectional Meetings, Committee on Trauma, Cancer Committee, Publications, Public Relations

Thursday, 8 00-9 30 a m

Breakfast Conference for Graduates and Administrative Residents of University Programs in Hospital Administration, and Course Directors Experience Exchange My First Year of Administering a Hospital

Thursday, 10 00 a m -12 30 p m

Theme—Discussion of Current Problems in Hospitals

SIXTH INTER-AMERICAN CONGRESS OF SURGERY

Chicago, Illinois, October 17 to 23, 1949

Separate Sessions - October 21, 22, and 23

THE Sixth Inter-American Congress of Surgery will be included in the Thirty-fifth Clinical Congress of the American College of Surgeons from October 17 to 21, with headquarters at The Stevens in Chicago, and will continue on October 21, 22, and 23 with its own business, scientific, and social sessions, most of which will be held in the John B. Murphy Memorial Auditorium of the College at 50 East Erie Street.

The following surgical societies, in addition to the American College of Surgeons, are members of the Association of Inter-American Congresses of Surgery:

Argentine Association of Surgery, Buenos Aires, Argentina

Bolivian Society of Surgery, La Paz, Bolivia

Brazilian College of Surgery, Rio de Janeiro, Brazil

Society of Surgery of Chile, Santiago de Chile, Chile

Society of Hospital Surgeons, Santiago de Chile, Chile

National Society of Surgery, Havana, Cuba

Society of Medicine and Surgery of Quito, Ecuador

Mexican Academy of Surgery, Mexico, D. F.

Indo-Latin College of Surgery, Mexico, D. F.

National Association of Medicine and Surgery, Panama

Society of Medicine and Surgery, Asuncion, Paraguay

Peruvian Academy of Surgery, Lima, Peru

Society of Surgery, Montevideo, Uruguay

The American College of Surgeons joined the association by vote of the Board of Regents on June 27, 1943. This action was preceded by an invitation from Dr. Luis Vargas Salcedo of Santiago, Chile, to send two delegates as guests of honor to the First Inter-American Congress of Surgery, held in Santiago November 15 to 19, 1942. Dr. Leo Eloesser, of San Francisco, attended as delegate, and it was upon his enthusiastic recommendation that the College joined the association. He also attended the second Congress, in Buenos Aires, October 10 to 15, 1943. Dr. Alton Ochsner, of New Orleans, was delegate to the third Congress, held in Montevideo,

Uruguay, October 1 to 6, 1946. No delegates were sent to the fourth Congress, held in Rio de Janeiro in 1947. Dr. E. Payne Palmer, of Phoenix, and Dr. Hu Crim Myers, of Philippi, West Virginia, were delegates and co-relators at the fifth Congress, held in La Paz, Bolivia, October 17 to 21, 1948.

Dr. Frederick A. Collier, who will be installed on October 17 as President of the American College of Surgeons, will, as President of the signatory society of surgeons in the host country, serve as President of the Sixth Inter-American Congress of Surgery. Dr. Arnaldo Caviglia, of Buenos Aires, is Secretary-General of the Association of Inter-American Congresses of Surgery, and will set up an office in Chicago prior to and during the meeting.

The Department of State of the United States of America has issued official invitations to the governments of the eleven other countries which have surgical societies belonging to the Association of Inter-American Congresses of Surgery, to send officially authorized delegates to the forthcoming Sixth Congress of Surgery. Most of the member societies have signified the intention of appointing delegates to the Congress and most of the co-relators have also been named.

THE PROGRAM

A preliminary outline of the program for the Sixth Inter-American Congress of Surgery follows:

Friday morning, October 21

Inaugural Ceremony

Address of the President of the Sixth Inter-American Congress of Surgery: FREDERICK A. COLLIER, M.D., F.A.C.S., Ann Arbor, President, American College of Surgeons

Report of the Secretary-General: ARNALDO CAVIGLIA, M.D., Buenos Aires, Secretary-General, Association of Inter-American Congresses of Surgery

Official Greetings: United States Government representatives

Greetings from the Signatory Societies: Official representatives to the Sixth Inter-American Congress of Surgery

AMERICAN COLLEGE OF SURGEONS

Friday, 12 00-1 30, October 21

Luncheon

Friday afternoon, October 21

Specialty panels of the Clinical Congress

Saturday morning, October 22

Main Theme Acute Cramiocerebral Trauma
Relator E JEFFERSON BROWDER, M D,
F A C S, Brooklyn, New York, U S A
Co-relators To be appointed by each member
country

Saturday afternoon, October 22

Main theme Treatment of Injuries in the Region
of the Ankle with Complications and
Sequelae
Relator HARRISON L McLAUGHLIN, M D,
F A C S, New York, New York, U S A
Co-relators To be appointed by each member
country

Saturday evening, October 22

Official Banquet

Sunday morning, October 23

Business Session
Luncheon

Sunday afternoon, October 23

Main Theme Pulmonary Carcinoma
Relator EVARTS A GRAHAM, M D, F A C S,
St Louis, Missouri, U S A
Co-relators To be appointed by each member
country

The following committees will aid in the ar-
rangements for the Sixth Inter-American Con-
gress of Surgery

THIRTEENTH CONGRESS, INTERNATIONAL SOCIETY OF SURGERY

(Société Internationale de Chirurgie)

New Orleans, Louisiana, U S A , October 9 to 15, 1949

THE following announcement has been received from Dr L Dejardin, Secretary-General of the International Society of Surgery

Plans for the Thirteenth Congress of the International Society of Surgery, which will take place in New Orleans, Louisiana, under the Presidency of Professor George Grey Turner, of London, England, are now in course of preparation

The scientific program was settled by the General Assembly at the last Congress in London, held in September, 1947. This body, at the recommendation of the Scientific Committee, also accepted two additional subjects, and decided who should open each discussion. The final arrangements were as follows

- 1 Surgery and Pathology of the Pancreas, Especially in Relation to Its Endocrine Function. Opened by PROFESSOR IAN AIRD, London
- 2 Surgery of the Parathyroid Glands. Opened by DR. PAOLUCCI, Rome
- 3 Surgery of the Suprarenal Glands. Opened by DR. M. R. FONTAINE, Strasburg
- 4 Pathology and Surgery of the Pituitary Glands. Opened by DR. M. P. MARTIN, Brussels
- 5 Treatment of Postoperative Thrombosis and Its Sequelae. Opened by DR. ALTON OCHSNER, New Orleans, and DR. MICHAEL DE BAKKEY, Houston
- 6 Causes of Recurrence after Operations on the Biliary Tract. Opened by DR. M. R. DEMEL, Vienna

In addition, the American Organizing Committee has arranged that two or three days of the meeting shall be devoted to the presentation of shorter papers on subjects of immediate interest.

The complete program, both scientific and social, will be circulated in due course

The program is being formulated by Vice President Evarts A. Graham, of St. Louis, Missouri

OFFICERS FOR THE BIENNIUM

GEORGE GREY TURNER, London, England, *President*
GORDON GORDON-TAYLOR, London, England, *Vice-President*

P. MATHIEU, Paris, France, *Vice-President*
R. DOS SANTOS, Lisbon, Spain, *Vice-President*
EVARTS A. GRAHAM, St. Louis, Missouri, U S A , *Vice-President*
SERGEI S. YUDIN, Moscow, U S S R , *Vice-President*
J. VERHOOGEN, Brussels, Belgium, *President of International Committee*
LEO A. M. DEJARDIN, Brussels, Belgium, *Secretary-General*
PAUL E. LORTHOIR, Brussels, Belgium, *Treasurer*
G. SPEHL, Brussels, Belgium, *Editor, "Journal International de Chirurgie"*
I. MIMS GAGE, New Orleans, Louisiana, *Secretary of the 13th Congress*

NATIONAL COMMITTEE FOR THE UNITED STATES

RUDOLPH MATAS, New Orleans, Louisiana, *Honorary Chairman*
ARTHUR W. ALLEN, Boston, Massachusetts, *Chairman*
ALFRED BLALOCK, Baltimore, Maryland, *Vice-Chairman*
W. BARCLAY PARSONS, New York, New York, *Secretary*
FREDERIC W. BANCROFT, New York, New York, *Treasurer*
HARRY H. KERR, Washington, District of Columbia, *Recorder*

ADVISORY COMMITTEE FOR THE UNITED STATES

CHARLES G. MIXTER, Boston, Massachusetts
ALLEN O. WHIPPLE, New York, New York
HARVEY B. STONE, Baltimore, Maryland
I. S. RAVDIN, Philadelphia, Pennsylvania
DALLAS B. PHEMISTER, Chicago, Illinois
EVARTS A. GRAHAM, St. Louis, Missouri
FREDERICK A. COLLIER, Ann Arbor, Michigan
ALFRED W. ADSON, Rochester, Minnesota
HOWARD C. NAFFZIGER, San Francisco, California
IRVIN ABELL, Louisville, Kentucky
DANIEL C. ELKIN, Atlanta, Georgia
ALTON OCHSNER, New Orleans, Louisiana

Inquiries should be directed to
DR. L. DEJARDIN, *Secretary-General*
International Society of Surgery
141, Rue Belliard, Brussels, Belgium

to preserve the sphincter mechanism at the lower end of the common duct

More than three decades ago one of Bevan's distinguished pupils, Evarts Graham, became interested in the problems of liver injury following biliary tract disease and in the repair of the liver subsequent to injury. In the intervening years we have come to know more of the changes which occur as the result of liver injury and of some of the factors which favorably influence repair. It is chiefly these problems which I want to talk about tonight. They must always be considered in the jaundiced patient who is being subjected to operation. Anyone who has studied the liver has come to know that of the three specially differentiated cells which constitute this organ (the hepatic or parenchymal cells, the cells of the bile ducts, and the reticuloendothelial cells), the hepatic cells are often the only ones to show evidence of severe, acute injury. The exception to this statement may be found in acute obstruction of the common duct associated with cholangitis. However, even under such circumstances, while the cells which line the ductal system may show severe evidence of inflammation, careful study of sections of the liver in patients suffering from cholangitis will usually show large masses of completely necrotic hepatic cells and other cells in such a state of degeneration that survival can occur only under particularly favorable circumstances. In the more chronic lesions, the hepatic cells are frequently involved in a number of processes, but the outstanding histologic change is an increase in the lobular fibrous supporting tissue.

Every clinician interested in hepatic and biliary disease has time and again seen a patient with every evidence of hepatic competency who became desperately ill within a few hours as the result of what normally is considered only a minor assault. No clear-cut delineation can now be made of the state that separates hepatic competency from incompetency. Even the results of the newer function tests are at times difficult to correlate with the changes observed upon histologic examination. The liver alone presents so serious an enigma, in its serious acute injury may coexist with evidence of vigorous regeneration. In fact, no other organ of the body possesses the ability functionally to regenerate itself under circumstances which are frequently far from the ideal.

It is important to remember that clinical jaundice in itself is of no serious consequence. The seriousness of jaundice is related to the conditions which initiated it and the factors which intensify and prolong it. In contradistinction to the jaundice associated with infectious hepatitis, the jaun-

dice of common duct obstruction may be associated with few, if any, untoward symptoms. In infectious hepatitis serious cellular injury can be demonstrated. In jaundice due to obstruction of the common bile duct without infection, extensive or even slight hepatic injury rarely is demonstrable. It is only when cholangitis intervenes that the patient becomes critically ill, and in such cases the seriousness of the illness is related to the virulence of the cholangitis and the extent of the hepatitis.

For years surgeons have talked and written of suppurative cholangitis, when in reality even a mild cholangitis is associated with varying degrees of hepatic degeneration and necrosis. The prolonged jaundice that is observed in patients who have been relieved of common duct obstruction but in whom parenchymal injury persists in spite of the fact that bile drains freely from a tube in the common duct is mute testimony of the persisting liver cell injury. Himsworth (16), in reviewing this aspect of the problem, has stated, "It would seem, therefore, justifiable to suggest that our attitude to lesions of the biliary tract should be reoriented. Cholangitis—or to speak more accurately, cholangio-hepatitis—would then be regarded as the central condition, mechanical obstruction to the large bile passages, if present, as a predisposing cause to this."

The primary conditions which confront the surgeon under these circumstances are the degree and virulence of the existing infection and the resulting parenchymal injury which these circumstances have imposed upon the patient.

It is incumbent upon the surgeon that he shall from the beginning of preoperative therapy, throughout the operation, and into the postoperative period surround the patient with those conditions which will prevent further injury and which at the earliest moment will facilitate repair. He must always assume a minimal margin of safety as regards functioning liver tissue. The sharp decline in prothrombin concentration from a relatively safe to a potentially dangerous level following anesthesia and common duct exploration, which is observed nearly daily in every large surgical clinic is an excellent example of the speed of change which may take place in the functional capacity. Whatever the degree of hepatic injury present at the time of operation, death, if it comes, is due usually to hepatic cell failure. This may be evidenced by hemorrhage, by hypoglycemia, by coma, or by a variety of other symptoms. It is evident that the condition of the liver as found at operation has become extended by further degeneration or necrosis, or both.

If we accept this concept, how can we so influence the pathological state which is present in the liver to decrease the morbidity and mortality of anesthesia and operation to the greatest extent?

The infecting organism in the majority of instances in cholangiohepatitis is a member of the colon group. Occasionally a streptococcus can be demonstrated. Zaslow, Counsellor, and Heilman have suggested that streptomycin may be ineffectual in assisting in the control of the infections associated with common duct obstruction. They have confirmed the studies of Zintel and his associates that streptomycin is excreted in the bile although the concentration in the bile does not reach that in the blood. Zaslow and his group found that as evidence of liver injury became more evident, especially in the presence of jaundice, little or no streptomycin appeared in the bile, except when the obstruction had been relieved. Our experience with the use of streptomycin has fortunately been happier than theirs. We have on numerous occasions used streptomycin with favorable influence on the objective and subjective symptoms of cholangiohepatitis. We have on a few occasions found sterile purulent material in the common duct at operation following streptomycin therapy. This has convinced us that this agent, when administered in adequate dosage, gains entrance to the liver and bile ducts and will frequently assist in the control of serious infection. Even though the surgeon is forced to operate in an emergency, the use of streptomycin will facilitate a more rapid control of the existing ductal and hepatic infection. In the chronic and recurring instances of cholangitis, streptomycin will frequently provide a sterile bile tract at the time of operation. Our limited experience with aureomycin, in a physician with an extensive and diffuse pylephlebitis with multiple abscesses, jaundice, and a positive blood culture due to an atypical diphtheroid, leads us to hope that this more recently developed antibiotic may prove to be of even greater value in the infections associated with cholangiohepatitis.

In a liver which is already the site of parenchymal cell injury as the result of pre-existing infection, further injury can be imposed by factors which detrimentally influence the blood flow to this organ. We have all observed the intense cellular changes which may occur between operation and autopsy. The mild degeneration and very limited areas of necrosis seen in the sections made from biopsy material removed at operation contrast strongly with the widespread degeneration and centrilobular necrosis found only a few days later at autopsy. These changes may at times be re-

lated directly to the anesthetic, which may have been a direct toxic agent, but they are more frequently related to circumstances that have imposed periods of oxygen deprivation on the parenchymal cells, which cells are exceedingly susceptible to oxygen deprivation.

Some years ago Goldschmidt, Ravdin, and Lucke (9) showed that when animals were subjected to anesthesia with hepatotoxic agents, the extent of the degeneration and necrosis induced by these agents could be modified favorably or adversely by varying the concentration of oxygen used with the anesthetic agent. Furthermore, degeneration and necrosis could be induced in the liver by exposing the animals to prolonged periods of low oxygen tension without the use of direct hepatotoxic agents.

The available evidence from many laboratories points strongly to the fact that an adequate and optimal oxygen supply is essential for the complete functional activity of the normal hepatic cell. The injured cell is more easily condemned to necrosis by any circumstance that alters a normal blood flow to the liver.

In 1937, Ravdin and Frazier called attention to the serious effects which at times may follow the sudden decompression of a completely obstructed common duct when the obstruction had been present for some time. The increased intraductal pressure coincident with obstruction impedes the portal blood flow and, to a lesser degree, the hepatic arterial circulation. If considerable fibrosis has taken place, the condition is still further aggravated. One of Bevan's colleagues, Herrick, showed in 1907 that the circulation of the liver was reduced greatly in cirrhosis. With the rapid release of the increased intraductal pressure an intense hyperemia in the liver is induced, and a still further impediment to the blood flow results. The degeneration and necrosis of parenchymal cells are multiplied to the extent to which further oxygen want is imposed by such a process.

Wakim and Mann demonstrated that the death of liver cells did not occur until 12 hours after rats had been exposed to the prolonged inhalation of volatilized carbon tetrachloride. Parenchymal liver cell necrosis occurs in a like period after ligation of the entire hepatic arterial supply, and so-called "liver shock," which in reality is an expression of a similar condition, rarely makes its appearance before the twelfth hour after operation.

Any circumstance which adversely affects physiological oxygenation of the hepatic cells may induce further injury. Severe anoxia due to the use of low concentrations of oxygen during anesthetization, prolonged periods of hypotension during

spinal anesthesia or in the recovery period, cyclopropane shock, and the failure to relieve gastric or intestinal distention may all condition circumstances favorable to further parenchymal injury.

Estrada, Simpson, and Vars have recently demonstrated massive or confluent centrilobular necrosis in the partially hepatectomized rat following exposure of the liver to massive gastric distention. The severity of the liver lesions which these workers produced was proportional to the strain to which the animals were subjected. A prolonged period of protein starvation accentuated the liver injury which they observed following gastric distention. Here again the adverse effect on the portal venous and hepatic arterial circulations manifested itself by extensive injury. I am not aware that any previous workers have demonstrated the importance of preventing distention, especially of the stomach, in the patient seriously ill with biliary tract disease. The demonstration that the more protein-depleted the rat was prior to operation and the greater the insult given it, the more frequent and severe was the resulting liver injury, clearly illustrates the importance of diet in the conditioning of liver injury even in the absence of direct hepatotoxic agents.

Thus, ductal obstruction with its resulting jaundice may cause little or no parenchymal injury and only minor physiological disturbances in the patient, while infection, anoxia, hepatotoxic agents, an inadequate diet, and distention may so alter the parenchymal architecture as to cause serious illness or even death of the patient.

Twenty years ago every surgeon was giving jaundiced patients glucose by the intravenous route, prior and subsequent to anesthesia and operation. It had come to be accepted following the investigations of Opie and Alford, Davis and Whipple, and others that a substantial increase in the liver glycogen would make anesthetization and operation safer. These workers had also shown that a diet containing a large amount of fat increased the susceptibility of the liver to chloroform. Nevertheless, for a period of nearly 20 years emphasis in regard to diet in the jaundiced patient was placed on the carbohydrate fraction of the dietary.

Goldschmidt, Vars, and myself (10) then demonstrated that glycogen per se did not protect the liver from injury. Our data led us to conclude that the incidence and degree of injury following anesthetization by chloroform increased with increasing concentrations of hepatic lipid regardless of the concentrations of hepatic glycogen.

The incidence and severity of the injury could be modified by the amount of protein present in the dietary for several days prior to anesthetiza-

tion. A high concentration of hepatic glycogen failed to confer any discernible protection against the hepatotoxic action of chloroform with the same concentration of hepatic lipid and a similar intake of protein in the diet. The protection against hepatic injury following a diet high in carbohydrate was found to be largely due to the reduction in the lipid content of the liver which resulted from such a diet.

A high protein diet prior to anesthetization with chloroform markedly reduced the incidence of hepatic cellular degeneration and necrosis, even in livers with a high lipid content, and therefore in the face of a severe attack by chloroform. Protein, moreover, proved to be an exceedingly active lipotropic agent. Starved animals exhibited the greatest degree of parenchymal cell injury, the incidence and degree of damage were always greater than in fed animals with the same content of hepatic lipid. These experiments suggested that the increased susceptibility of the starved animals was very likely due to their depleted protein stores, for such animals will lose as much as 20 per cent of the liver protein within 24 to 48 hours and as much as 40 per cent in 7 days (1). The direct protection against injury by protein was, in our opinion, due to some "component or components of the protein molecule." Miller, Ross, and Whipple (20) soon showed that methionine was the most important fraction of the protein molecule providing this protection in the protein-depleted dog.

The influence of diet in conditioning liver injury without the addition of direct hepatotoxic agents has more recently received widespread attention (12, 16, 18). In 1935 Weichselbaum showed that rats fed for several weeks on a diet low in protein suddenly became ill and died. He further showed that the condition could be prevented by adding cystine or methionine to the dietary. The early histologic appearance of the livers of the animals suffering from such a deficiency was one of marked hyperemia and degeneration and necrosis of the hepatic cells, continuing on to acute massive necrosis.

Himsworth (15) believes that a similar circumstance occurs in man. He states, "The original reluctance to accept a severe lesion like dietetic massive necrosis as the result of a nutritional deficiency has now been largely removed by appreciating the part played by circulatory factors in its production. It is only necessary to postulate that the deficiency leads eventually to severe swelling of the hepatic parenchyma for, once such is produced, the peculiar circulatory arrangements in the liver will automatically ensure the development of a lesion with the characteristics of mas-

sive necrosis." The interrelationship of diet and the integrity of the cellular blood supply received new emphasis from these studies.

The advantages of providing a diet before and after operation on patients with jaundice and liver injury, which contained an adequate amount of a complete protein and ample carbohydrate seemed obvious. The protein stored or elaborated into hepatic and other body tissue served, on the one hand, to protect the hepatic cells from further injury and to replenish a structure already attacked.

The so-called labile protein which is rapidly lost during starvation is rapidly replenished by adequate feeding. Miller (19) has recently reported that the loss of protein from the liver was related to the loss of certain enzyme activities. Schultz has shown that in the course of a 6 day fast there was close to a 50 per cent loss of liver weight and liver nitrogen along with an average loss of body weight of only 10 per cent. The enzyme activity of the liver which Schultz studied was decreased by 66.6 per cent during the 6 day fast. The importance of normal enzyme activity in maintaining cell integrity is now well recognized. These studies provide an additional explanation of the physiological deficiencies which occur in the liver during protein starvation.

Studies of the human liver from specimens taken by us at operation showed that unusually large increments of lipid were frequently present in the livers, especially those of patients with cholangiohepatitis. The presence of large increments of fat in these patients may be a predisposing factor, in addition to infection, in the production of the hepatic fibrosis which certain of the patients develop with enlargement of the spleen, ascites, and even hematemesis. It seemed highly desirable that such excess hepatic lipid be released from the liver prior to operation and kept out of it later.

It was upon such evidence and reasoning that we suggested the high carbohydrate, high protein, low fat diet as a means of preparing the patient with cholangiohepatitis for operation. When this dietary was used in patients in whom we had reason to believe from our earlier studies that excess lipid existed in the liver, the lipids found in the liver at operation were at, or only slightly above, the normal level. We became convinced that such patients did better after anesthesia and operation. We gained the impression, based purely on clinical response, that recovery was facilitated. The surgeon's responsibility does not cease with the removal of one or more common duct stones or the successful excision of a disabling stricture. In the cure of the patient regeneration of the damaged parenchyma, once the obstruction of bile flow and

the infection are relieved is of fundamental importance.

There are indeed evidences in infectious hepatitis and more rarely in the milder types of cholangiohepatitis, that the two processes of damage and repair proceed at the same time under favorable conditions.

The older literature on liver regeneration is concerned chiefly with the total liver mass and with morphology. Relatively little was known regarding the chemical composition of the liver during repair. The pioneer study of Higgins and Anderson on regeneration in terms of total liver mass included some values for the water component. Also, very little was known concerning the behavior of liver protein after partial hepatectomy. The latter is important from a number of viewpoints. Walter and Addis had suggested that the protein content of the liver, rather than the organ's total mass, is the measure of effective liver size. Since regenerating parenchyma requires protein components for cell synthesis, it seemed interesting to determine the rate of regeneration on a normal diet, on abnormal diets, and on dietaries containing proteins known to be deficient in certain essential amino acids.

It was found by Gurd, Vars, and myself that during a 14 day interval after partial hepatectomy both protein-fed and nonprotein-fed rats regenerated liver tissue which was essentially normal in gross composition. Water, glycogen, lipid, and protein were all incorporated into the new liver substance in relatively normal proportions, although at varying rates.

The rate of appearance of new liver protein was most rapid during the first 2 days in both the protein-fed and protein-starved groups which suggested that survival indeed depended upon rapid regeneration, as well it may. The higher the concentration of an adequate protein (casein) in the diet, the more rapid and complete the regeneration of the liver. The difference in rate and completeness of regeneration closely paralleled the amount of protein available. The necessity of the protein-starved group to obtain protein for regeneration from endogenous sources greatly limited complete repair. Nevertheless, the increment of liver protein formed by the protein-starved group represented an increase of almost two and one-half times the liver protein present at the close of the partial hepatectomy. In both groups the increase in liver protein between the eighth and fourteenth days was small. Only when the diet consisted of casein in amounts of 50 per cent of the total calories was a significant increase obtained. Under these circumstances the most nearly com-

plete regeneration of the original protein was achieved. It is interesting to note that Cole found such high protein diets of great help in overcoming protein deficits in surgical patients.

An outstanding fact was that protein-starved rats regenerated liver tissue by utilizing protein solely from endogenous sources. The fact that the liver protein reached a plateau after 8 days suggests that an equilibrium was reached between the liver and body tissues when a certain level of regeneration was obtained. It would seem as if the emergency needs of the liver to replace its own deficiency of protein having been met, other body tissues participated more actively in their demands for protein.

The data are interesting also because they contain evidence suggesting that the rate of regeneration may be greater in the case of greater need. The most rapid rate of regeneration was during the first 2 postoperative days. The percentage increase in the rate of appearance of new liver protein in the first 2 days was greater in the protein-starved animals than in the animals fed casein before and after operation. Such a circumstance strongly suggests a more potent stimulus to liver recovery in the animals with an initial more severe reduction of liver substance. Survival may indeed have been dependent upon the ability of such livers more actively to express their urge to regenerate even under unfavorable circumstances.

In an extension of these studies it was found that the ingestion of 5 per cent of casein in the diet, although inadequate to prevent weight loss or to keep the animals in positive nitrogen balance, led to a substantial increase in the liver protein following hepatectomy. At higher levels of protein intake the increase in body weight and liver protein appeared roughly parallel. Attention should be directed to the animals fed 5 per cent casein with and without methionine. Without showing a gain in body weight they all displayed a significant increase in regenerating liver protein over that in the rats on the nonprotein diet. While progressive increases in the intake of an adequate protein were associated with progressive increases in the amount of liver protein laid down, the introduction of methionine at a 1 per cent level into each such dietary appeared to augment the effect of the protein alone to a small but consistent degree.

The feeding of other proteins at dietary levels isonitrogenous with the 10 per cent casein diet led to widely varying effects. Gelatin and zein led to no more regeneration of liver protein than occurred on a nonprotein diet. These data illustrate the fallacy of depending on nitrogen balance studies. Wheat gluten resulted in a moderate in-

crease. Liver protein was comparable to casein. Fibrin and whole egg protein led to a greater amount of new liver protein than did casein at the same dietary level. The quality of the ingested protein was of importance in facilitating complete repair.

The degree of regeneration of liver protein occurring in previously protein-starved animals may be greatly enhanced by postoperative protein feeding in proportion to the level and the biological value of the protein fed.

There are certain inherent difficulties in the feeding of a diet, either to the experimental animal or man, in which dietary fat is excluded or limited to a very great extent. Not only are necessary dietary components important in a nutritional program, but the ingestion of a sufficient number of calories is equally important. In both the experimental animal and, to a greater extent, in man the total food consumption and therefore the caloric intake is increased by the addition of fat to the diet.

Several years ago Hoagland raised the question as to whether it was necessary that dietary fat be greatly restricted in patients with, and recovering from, infectious hepatitis.

In our earlier studies we had indeed obtained some data which demonstrated that this was possible. In our later studies of liver protein regeneration and nitrogen metabolism the diets used were made to contain only 3 per cent of fat, which provided 7 per cent of the calories. The work of Fox, Swift, and their associates (7, 8), of Deuel and of others suggests that the inclusion of adequate amounts of fat in the diet improves utilization of energy and the physical fitness of normal animals. Vars, Friedgood, and I have more recently investigated the effect of adding 10 per cent and 30 per cent of a good fat to a nonprotein diet and to diets containing casein upon liver protein regeneration and nitrogen metabolism after partial hepatectomy.

An increased percentage of fat calories in a nonprotein diet did not increase the conservation of nitrogen as measured by liver protein regeneration, although it decreased the negative nitrogen balance somewhat. A good fat added to a protein diet in which the protein to fat calorie ratio remained constant caused a greater food intake with an associated increase in liver protein regeneration and a more positive nitrogen balance. This was also true in controls not operated upon. Ingestion of an increased percentage of calories as fat during a period of isonitrogenous, isocaloric feeding produced an equal amount of, and in some instances an increase in, liver protein regeneration.

as when fat was restricted Liver protein regeneration also occurred even when the liver became excessively fatty after removal of choline from the diet

When the liver is to be exposed to hepatotoxic agents with necrotizing action which is intensified by the presence of large increments of hepatic lipid, a diet in which fat is somewhat restricted may still be advantageous Our data would suggest, however, that when proteins of good quality containing adequate amounts of methionine, cystine, and choline are incorporated in the dietary, there occurs no increase in the liver lipid content, but a substantial increase in liver protein Surely during periods of recovery when attempts are being made to stimulate liver regeneration, the addition of an adequate fat to an otherwise satisfactory ration would appear now to be highly desirable and should be adopted in the care of patients with liver disease

I would have enjoyed discussing with you many of the other problems associated with surgical jaundice They are numerous and important, but their pathologic physiology is in many instances not yet clear I therefore preferred to talk about several aspects of the subject about which, as the result of the work of many investigators, more is known These data provide a rational basis for improving the condition of the liver prior to, and subsequent to operation If generally accepted, they should lead to reduction of the morbidity and mortality of operations on the biliary tract associated with jaundice and to reduction of the incidence of disabling fibrosis of the liver due in part to deficiencies of a dietetic nature and to infection

While Bevan himself did not participate in such studies, his intellectual descendants have added immeasurably to our fuller understanding of a wide variety of man's diseases, and their contributions to our knowledge of the pathologic physiology of biliary tract disorders are of great importance

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Ocular Signs in Head Trauma ARTHUR B. KING and FRANK B. WALSH *Am J Ophthalm*, 1949, 32 379

In prefrontal lobotomy the anterior oculogyric pathways are seldom interrupted so that deviation of the eyes rarely follows. In the parietal lobe, bilateral trauma of the angular gyri results in spatial agnosia. At the level of the temporal lobe interruptions of the optic radiations produce sector defects or complete homonymous hemianopsia with or without macular sparing.

Removal of one occipital lobe results in hemianopsia but the associated interference with the fixation reflex may account for sufficient unsteadiness of fixation so that sparing of the macula results. In more anterior lesions the optic fixation reflex is not impaired and splitting results. Cortical control of convergence and divergence has not been proved by injury cases, but the divergence during sleep, anesthesia, and trauma supports this concept. Visual hallucinations, when formed, point to the temporal lobe, but when they are but a vague sensation of light the occipital lobe is probably involved.

Injuries to the brain stem produce transient ocular muscle palsies. Ptosis is not uncommon. Conjugate deviation of the eyes of pontine origin tends to be permanent while that of cortical origin tends to be transient. Persisting nystagmus points to brain stem damage.

In carotid-cavernous sinus fistula, the detection of a bruit must be accompanied by engorgement of ocular vessels or proptosis to establish the diagnosis. The globe pulsates synchronously with the heart beat. Papilledema in the affected eye occurs late. Ligation of the internal carotid artery produces a cure generally.

In extradural hematoma from ruptured middle meningeal artery there is early a sluggish pupillary light reflex on one side, later there is inequality and a dilated fixed pupil. Incomplete ptosis or divergent strabismus may be present. After 24 hours papilledema may be noted. When both pupils become dilated and fixed, death is near.

Chronic subdural hematoma often shows an enlarged pupil sluggishly reacting to light, if at all. Papilledema develops late. Subhyaloid retinal hemorrhages are commonly seen in infants but almost never in adults.

Echymosis of the lids and conjunctiva seen in basal skull fracture is distinguished by several features: the extravasated blood makes a circle limited by the palpebral fascia to the orbital margin, the discoloration is purplish from the beginning, the hemorrhage is subconjunctival and shows no pos-

terior limit, and the blood is first seen in the lower lid at the medial border.

Subarachnoid hemorrhage should be treated conservatively. Ventriculograms, encephalograms, and arteriograms are not recommended in the acute stage of head injury. Operative intervention is indicated for the evacuation of collections of blood, and for the repair of compound and depressed fractures. Subtemporal decompression for increased intracranial pressure has questionable value.

JAMES E. LEBENSOHN, M.D.

The Eyes in Mongolism RONALD F. LOWE *Brit J Ophthalm*, 1949, 33 131

Retardation of growth in mongolism affects the whole body. The small maxillae and orbital ridges cause the flattened appearance of the face. The short sagittal diameter of the skull changes the inclination of the orbital axes from the normal 45 degrees to about 75 degrees. The mongoloid palpebral features are characterized by epicanthus, obliquity, shortness, and an even arch of the upper lid margin—all due to a developmental disturbance of the surface ectoderm. Alopecia is moderately common.

The iris frequently shows poverty of the stromal fibers in the outer third of its surface, and in blue irides there is peripheral pigment speckling in the form of small golden or whitish splashes. In adults the eyes are set about 5 mm. closer than normal, the average interpupillary distance being 55 mm. The pupils are normal.

Cataractous changes of various types are commonly seen after the age of 8. The slit lamp may show arcuate opacities in the deepest layers of the fetal nucleus, and dustlike and flake opacities in the infantile and adult nucleus. About 1 in 4 eyes reveal opacities of the Y sutures of the fetal nucleus. The arcuate opacities are opaque lens fibers, probably caused by abnormalities in the regressing tunica vasculosa. The flakes are of two types: (a) minute dots internal to the equator and more peripherally and (b) equatorial white spokes resembling the usual coronary cataract. The ordinary congenital cataract may also be present in the lamellar, disc shaped, and posterior polar types. Myotonic cataracts superficially resemble those in mongolism but involve the cortex especially and advance rapidly to maturity.

Congenital myopia occurs in one third of the cases. Nystagmus is common and is associated generally with lens opacities or high myopia, the exclusion of suitable retinal impulses preventing the development of the fixation reflex. Convergent strabismus affects more than half of the cases. Divergent strabismus or vertical deviation does not occur. Abduction weakness is frequently seen with congenital myopia.

SURGERY OF THE HEAD AND NECK

Mongoloids are very susceptible to infection of all mucous surfaces. The conjunctiva, respiratory and gastrointestinal tracts are particularly susceptible. Intraocular infection is rare.

The developmental anomalies suggest that the disturbance begins very early in fetal life, probably in the first 4 to 8 weeks.

Studies in Experimental Ocular Tuberculosis Effect of "Promin" and "Promizole" in Experimental Ocular Tuberculosis in the Normal Rabbit ALAN C. WOODS and EARL L. BURKY
Arch Ophthalmol, Chic, 1948, 40: 1

The authors have previously shown that promizole and promine exert a strongly deterrent effect on ocular tuberculosis in immune-allergic rabbits. The current experiments were performed on normal animals that had not developed an immunity to reinfection. The anterior chambers were inoculated with a virulent human strain of tubercle bacilli, and equal groups were observed as controls or were treated with promine or promizole.

Clinically a slight deterrent action of the drugs was noted after 2 weeks of treatment and this was somewhat more pronounced after a period of 8 weeks. Histologically there was but slight difference in the degree and the extent of the disease in the eyes of treated and control animals. All transmission experiments with the treated animals gave positive results indicating that large numbers of living virulent bacilli were still present in the uveal tracts. It is concluded that promine and promizole have a limited bactericidal effect on the tubercle bacillus which becomes evident only when the tuberculous process is so restrained by a systemic immunity that it is brought within the therapeutic range of the compounds.

FRANK W. NEWELL, M.D.

Motor Block of Extraocular Muscles by Deep Orbital Injections HAROLD GIFFORD, JR. *Arch Ophthalmol*, Chic, 1949, 41: 5

The author gives a detailed description of the anatomy of the orbit with specific details as to the position of the motor nerves and muscle cone. He favors a more complete retrobulbar anesthesia for extraocular muscle paralysis to prevent the loss of vitreous in intraocular surgery.

The method used by him requires a 5 cm needle, No. 25 (Becton Dickinson). It is inserted through the skin just inside of the lower temporal rim of the orbit. It is directed toward the apex of the orbit so that it goes through Tenon's capsule midway between the lower edge of the external rectus muscle and the lateral edge of the inferior rectus muscle. The needle is plunged through the fascia into the muscle cone and is "floated" back from here toward the upper lateral corner of the orbit. The needle is plunged in 5 cm. Two cubic centimeters of 2 or 4 per cent procaine hydrochloride with 0.4 c.c. of adrenalin to the ounce is used. If complete anesthesia is not obtained with the first cubic centimeter the

needle is withdrawn slightly and re-inserted to reach the active muscle, and more anesthesia is injected.

Fractures of the Orbital Floor ARTHUR GERARD DEVOE *Arch Ophthalmol*, Chic, 1948, 39: 595

In this article the author presents 34 cases in which the late treatment of orbital floor fractures was discussed.

Such repair is best carried out by the ophthalmologist, and may take the form of operation on the extraocular muscles or substitution of inert substance in the orbital floor in order to restore orbital volume or elevate the globe to proper position. The inert substance may be cartilage, spun glass, bone, vitallium, or tantalum.

The early treatment of orbital fractures is discussed in a review of the recent literature because most of the patients were treated by surgeons other than ophthalmologists.

EARL H. MERZ, M.D.

A Fundus Dystrophy with Unusual Features (Late Onset and Dominant Inheritance of a Central Retinal Lesion Showing Edema, Hemorrhage, and Exudates Developing into Generalized Choroidal Atrophy with Massive Pigment Proliferation) ARNOLD SORSBY, MARY E. JOLL MASON, and NORMAN GARDENER *Brit J Ophthalmol*, 1949, 33: 67

This is a carefully prepared, exacting report on 5 families whose members showed certain similar ocular characteristics designated as a fundus dystrophy.

- 1 The affection was dominant in character.
- 2 It became manifest at about the age of 40.
- 3 It began as a central lesion showing edema, hemorrhage, and exudation. This was followed by atrophy and excessive pigmentation involving the entire choroid.

The condition in all of the family members followed the same pattern and offered a poor prognosis. The choroid was the diseased tissue. This condition seems to be a clear cut disease entity.

EARL H. MERZ, M.D.

Mycotic Infection of Eye HUGH C. DONAHUE *Am J Ophthalmol*, 1949, 32: 207

Concretions of the canaliculi due to fungus infection have been frequently noted but mycotic involvement of the lacrimal sac and duct is rare. Such infection from *Aspergillus niger* has not been previously described. Of the *Aspergillus* family, only the species *fumigatus* and *niger* are pathogenic to man. Infection occurs most often in those exposed to fungus spores, such as bird feeders, fur cleaners, and agricultural workers.

The case reported concerned a 12 year old girl who complained of left epiphora and discoloration of the conjunctival aspect of the medial angle of the left lower lid. Around the lower punctum was a discoid, brown-black elevated area, 1 cm in diameter. The punctum itself was completely occluded by a black substance which resembled the tip of a lead pencil.

No fluid could be irrigated into the nose from the upper punctum, and pressure on the lacrimal sac yielded no discharge. After a tiny incision over the lower punctum a sticky tenacious molasseslike fluid was expressed with complete disappearance of the previous discoloration. Fluid was then easily irrigated through either canaliculus into the nose. Permanent recovery from the symptoms followed.

Direct examination of the material showed mycelium fragments and numerous spores. Culture on Sabouraud's dextrose agar gave a growth of typical *Aspergillus niger* with the characteristic conidiphores and spore changes.

Role of Inheritance in Glaucoma ADOLPH POSNER and ABRAHAM SCHLOSSMAN *Arch. Ophthalm., Chic.*, 1949, 41: 125

Of 373 unselected patients with primary glaucoma, 51 belonging to 30 families had one or more relatives affected with the disease. In many families there were similarities in the behavior of the disease with respect to type, refractive error, severity, and response to surgical treatment. All the pedigrees showed dominant heredity except one in which it may have been recessive. The pedigrees of 28 of the 30 families are included.

FRANK W. NEWELL, M.D.

The Technique of Goniotomy for Congenital Glaucoma OTTO BARKAN *Arch. Ophthalm., Chic.*, 1949, 41: 65

This article explains in detail the technique of goniotomy for the treatment of congenital glaucoma. The embryonic tissue in the angle is peeled or stripped away to allow free access of the aqueous to the drainage system in the anterior angle.

In 66 of a total of 76 eyes, pressure was normalized and vision was maintained or restored. Early surgery is certainly advantageous.

The mode of action, and the indications, contraindications, and technique of goniotomy are discussed.

EARL H. MERZ, M.D.

Necrosis of the Intraocular Tissues BERNARD SAMUELS *Arch. Ophthalm., Chic.*, 1948, 40: 101

The present article on necrosis of intraocular tissues is based on a series of 800 eyeballs which presented microscopically visible necrotic tissue.

Degeneration, atrophy, and gangrene are associated with necrosis. Degeneration signifies alteration in the metabolism of the cells of a tissue, atrophy denotes diminution in the size of cells or of tissues after maturity. Degenerated or atrophic tissue may be converted into necrotic tissue. Gangrene denotes necrosis which follows invasion by saprophytic organisms. Necrosis means the local death of cells or of tissues in an organ which continues to live.

There are two types of intraocular necrosis—non-inflammatory and inflammatory.

In the noninflammatory type, necrosis may be caused by circulatory disturbances (1) in iridod-

alysis, when the arteries, veins, and nerves of the iris are severed from their connection with the ciliary body, (2) in cyclodialysis, when the anterior ciliary arteries are severed, part of the ciliary muscle becomes necrotic, (3) in glaucoma, when the blood supply is arrested the iris and the ciliary processes become necrotic.

In the inflammatory type, the necrosis is caused by the toxins of pyogenic bacteria which may be *exogenously* located in the cornea. The toxins from a serpiginous ulcer may diffuse into the aqueous to set up a condition of intoxication which is severe enough to cause necrosis of the iris and hyperemia of the blood vessels of the ciliary processes and even of those of the retina. Bacteria may also be located *endogenously* (a) in the anterior chamber, setting up an infection in contradistinction to an intoxication, and (b) in the vitreous body. Infection confined to the anterior chamber is far less serious than that which is located in the posterior chamber or in the vitreous, because the ciliary body is affected in the latter. Bacteria within the vitreous create toxins which irritate the ciliary body and retina, and cause migration of pus cells from the ciliary processes toward the bacteria in the vitreous to form an abscess (endophthalmitis septica). Panophthalmitis septica is characterized by total and widespread tissue necrosis in which no part of the eye escapes.

Necrosis may be caused by the retention of lens matter. The necrotizing effect on the iris and cornea of a large amount of lens matter resembles that caused by colonies of bacteria.

Necrosis caused by trauma is exemplified by damage to the cornea by heat arising from hot metal, or by strong acids.

Neuropathic necrosis, or neurokeratitis paralytica, may occur in herpes of the iris, and is characterized by eruptive, circumscribed, reddish elevations on the surface of the iris, similar to those on the skin. The pathologic picture is characterized by plastic iridocyclitis and an excessive amount of necrosis in the stroma of the iris, which is identical with the inflammatory toxic type of necrosis that is produced by pyogenic bacteria.

In acute primary necrosis of the uvea, bacteria, glaucoma, and trauma (conditions known to produce necrosis) are excluded.

Necrosis of a malignant melanoma of the choroid may cause necrosis of pre-existing tissues. Spontaneous death of an intraocular malignant melanoma is the common fate of all neoplasms. Resultant toxins may set up an iridocyclitis and glaucoma resembling an acute fulminating glaucoma.

The larger the melanoma, the more likely it is to become necrotic. Most tumors are composed of different types of cells—spindle cells in one part and round cells in another. Groups of dead cells are present in almost every melanoma. In some tumors, bands of connective tissue surround necrotic areas.

Necrosis of pre-existing tissues is described. In necrosis of the sclera, the sclera may be replaced by pus which discharges into Tenon's capsule. In

necrosis of the choroid the normal part of the choroid is the least likely of all the layers of the eye to undergo necrosis. In necrosis of the retina the highly organized retina succumbs to virulent toxins, and "falls to pieces" (the ora serrata is particularly vulnerable). In necrosis of the papilla the papilla may be converted into an indefinite weblike groundwork lying over the lamina cribrosa. In necrosis of the ciliary body the nonpigmented layer disappears completely. In necrosis of the iris the side of the iris next to the tumor is more affected. In necrosis of the vitreous and zonule these structures have no resistance. In necrosis of the lens the lens capsule is invariably distended.

Necrosis may be artificially induced as a therapeutic measure in irradiation for retinoblastoma, and by diathermy for detachment of the retina.

JOSHUA ZUCKERMAN, M D

Use of Pooled Human Vitreous MILO H. FRITZ *Am J Ophthalm*, 1949, 32 45

This study deals with the experimental injection into the human eye of pooled human vitreous. One of the problems was to determine the bacteriological status of the material to be used. The source of the vitreous represented eyes donated to the Eye Bank, which for various reasons had been rejected as unsuitable for use in corneal transplants. The technique was not complicated, the essential feature being to obtain clear vitreous. The purpose was to determine if vitreous substitution could be made in cases of cloudy vitreous due to hemorrhages or inflammatory reactions, and in hypotony following cataract surgery or retinal detachment operations.

It was established that pooled human vitreous could be stored at temperatures ranging from 32° to 50° F without any loss of clarity. It was further established that from 1 to 15 cc of vitreous could be injected into an eye without any great reaction or interference with vision. The tension remained about the same for 10 months when there was no further reason for loss of tone. Cerebrospinal fluid was also successfully used as a vitreous substitute.

J WOODHULL OVERTON, M D

Retrolental Fibroplasia WILLIAM COUNCILMAN OWENS and ELLA UHLER OWENS *Am J Ophthalm*, 1949, 32 1

Retrolental fibroplasia was described in Terry in 1942. It is seen in premature infants and characterized by an opaque, vascular membrane against the posterior surface of the lens. Terry thought the disease developed after birth because of the development of embryonic connective tissue. Reese and Payne, however, thought it was a congenital disease.

The incidence of retrolental fibroplasia in the present series was based on regular examinations of premature infants weighing 4.5 lb or less. There were 214 in the series, 40 weighing less than 3 lb, and 174 weighing between 3 lb and 4.5 lb. The authors did not find any cases at birth. They examined the infants for a period of 6 months or more

and found an incidence of 12.1 per cent in those weighing under 3 lb and one of 1.3 per cent in the group weighing more than 3 lb.

All visible remains of the hyaloid system disappeared. The dilatation and tortuosity of the retinal arteries and veins were the first signs, the veins becoming 3 times their normal size. Then there were grayish yellow elevations of the retina in the periphery, the disc became blurred, and there was a generalized retinal edema. This was followed by formation of a grayish membrane and vessels in the periphery of the retrolental space. A yellowish red reflex was observed. Finally a complete retrolental membrane was formed. Broad ciliary processes were observed on the membrane, which was also vascular. The eye appeared smaller, the anterior chamber was shallow, posterior synechias formed, and the iris was atrophic. In some cases a secondary glaucoma developed.

The onset of the disease occurred between the second and fifth months.

These studies do not coincide with Terry's theory of a fibroplastic overgrowth of the hyaloid artery and tunica vasculosa lentis, nor with the theory of Reese and Payne, who thought the lesion was due to a persistence of the primary vitreous. The authors believe the lesion is a postnatal development characterized by an angiomatous dilatation of the retinal vessels followed by a gross retinal detachment. The etiological factor has not yet been determined.

J WOODHULL OVERTON, M D

Scleromalacia Perforans Report of a Case MELVIN HARBATER *Arch Ophthalm*, Chic., 1949, 41 183

Scleromalacia perforans is an insidious degenerative disease of later life characterized by holes in the sclera producing exposure of the uvea. It is usually accompanied by rheumatoid arthritis. The lesion begins as a small sterile abscess surrounded by epithelioid cells, and after a variable period the contents of the abscess are extruded and the uvea is exposed.

A case is reported in a white female, aged 70, who had rheumatoid arthritis since the age of 30. Vision was markedly reduced, there was severe photophobia and numerous posterior synechiae preventing dilatation of the pupil. Four millimeters superior to the limbus in both eyes, there were scleral holes from 3 to 4 millimeters in diameter. Marginal necrosis of the cornea was present. Local administration of penicillin resulted in subjective improvement but did not modify the progress of the disease. In the course of 20 months most of the anterior portion of the sclera became necrotic. The right eye was enucleated and the left eye became blind from an associated uveitis.

FRANK W. NEWELL, M D

The Blindspot Syndrome KENNETH C. SWAN *Arch Ophthalm*, Chic., 1948, 40 371

In a series of 296 cases of esotropia, observed in the clinics of two medical schools, 102 were found to have in common certain symptoms and signs which

have been designated as the "blindspot syndrome." For distant fixation, the physiologic blindspot of the deviating eye was found to overlie the point of fixation in 85 cases; i.e., the deviation was from 12 to 18 degrees. The physiologic blind-spot was only part of a suppression scotoma and its position was inconstant, however, there were cases in which it seemed probable that the physiologic scotoma provided the essential mechanism for alleviation of diplopia and played an important role in maintaining the esotropic state. This group of cases seemed to represent a clinical entity which was designated as the "blindspot syndrome." Since the initial report of 7 cases was submitted, an additional 95 cases have been observed.

The most significant symptom was periodic diplopia, the history of which was seldom volunteered because in only a few cases was the diplopia annoying, but it could be elicited in 75 of 102 cases. In every case, homonymous diplopia could be created under ordinary visual conditions by the use of prisms just large enough to shift the rays of light off the blind-spot of the squinting eye. The most obvious sign was concomitant esotropia of from 10 to 20 degrees. The average deviation was from 14 to 16 degrees for distant fixation. The deviation was proportionately greater for near vision, but greater variations were found. In 62 cases, a hypermetropia of more than 2 diopters or anisometropia of more than 1 diopter was present.

Normal retinal correspondence seems a consistent feature of the blindspot syndrome. It was demonstrated as being present in all of the cases by the usual methods of examination. Potentially available or immediately demonstrable good fusion was considered as part of the syndrome. In less than half of the cases, the initial examination revealed fusional movements of appreciable degree at the angle of deviation, however, after sensory and motor fusional ability was established, orthoptic training was feasible in all of the cases. The blindspot syndrome may develop spontaneously in association with an uncorrected refractive error. It may also be acquired after a partial correction of a larger degree of esotropia, either by glasses or surgically. Occasionally, it may develop after a period of occlusion of an amblyopic eye or in association with the establishment of normal retinal correspondence. The syndrome does not seem to develop in the presence of anomalous retinal correspondence; at least it cannot be demonstrated to play a role in the alleviation of diplopia in such circumstances.

The prognosis of restoration of single binocular vision is excellent. It is necessary to correct the refractive error, to establish an ample range of fusional movements before operation, to correct fully the deviation by surgical means, and then to follow operation with orthoptic training in order to establish a reserve of fusional movements adequate to overcome any residual deviation without undue stress on the accommodation-convergence mechanism.

MICHAEL LOUVALIAN, M.D.

Subretinal Drainage in Retinal Detachment

DR. W. DE ROETHEN, Sr. *Am J Ophth*, 1940, 3: 55

In retinal detachment, the subretinal fluid is drained off or absorbed by the choroid which allows the retina to come in contact again with the choroid. It is thought the hypotony occurring in detachments is due to this absorption. The condition of the choroid vessels is an important factor in the absorption.

Many surgical procedures to remove the subretinal fluid have been attempted, they include scleral puncture, trephine, sclerectomy, iridopuncture, and aspiration with a hypodermic syringe. Later, thermocautery was used. More recently, surface and perforating diathermy have been used. One of the problems involved when no tear is present is to get sufficient drainage over a period of time, as the openings in the sclera and choroid tend to close off. If a retinal tear is present, the fluid is absorbed by the choroidal vessels after the tear is sealed, provided the vessels are functioning.

Surface diathermy is performed and a drain is placed in position through the sclera and choroid for from 1 to 2 weeks. Hemorrhage is a complication to be reckoned with when the choroid is punctured. Air is injected into the anterior chamber to increase the preretinal pressure and force the retina back against the choroid.

The article is summarized as follows:

1. Subretinal hemorrhage occurred in 3 of 7 eyes that were operated upon.
2. The risk of a sympathetic ophthalmia should be considered.
3. In 3 of the 7 eyes the retina was reattached.
4. A normal choroid absorbs subretinal fluid and produces a fibrin which helps to reattach the retina.

J. WOODHULL OVERTON, M.D.

Surgical Treatment of Retinal Detachment

P. VERDAGUER, *Am J Ophth*, 1940, 3: 63

The author limits his discussion to cases of retinal detachment in which there is a fair chance for good results, namely, idiopathic cases occurring in myopia, senility, or disinsertion of the ora serrata, as well as traumatic cases.

The fundus examination before and during surgery is very important since the tear in the retina must be localized and sealed off. The search for the tears should be extensive and thorough. The location and prominence of the detachment suggest the location of the tears. They are usually found near the equator.

In localizing the tear, the author uses a fundus chart to determine its meridian and the number of disc diameters from the ora serrata.

Preoperative care is important and rest in bed with both eyes bandaged for a week is a good policy. The operative treatment requires adequate exposure and the application of diathermy.

Surface diathermy is applied in the preretinal areas, and the intensity is controlled to give a pinkish appearance. In general, from 50 to 100 m are used. The electrode is 1 mm in diameter and held

applied to a dry globe. The next step is to drain off the fluid with a puncture needle, but each coagulation should be stopped when fluid appears. Then gentle suction may be applied. The points of coagulation are made 3 mm apart and completely encircle the tear.

Three types of detachment should be considered in addition to the one we have mentioned: (1) detachment or disinsertion of the retina at the ora serrata, (2) detachment due to tear at the macula, and (3) detachment due to aphasia. In the last type, a new approach was attempted. After the surface coagulation, the sclera was incised and a fine silk suture passed through the lips of the sclera to include the deep layers. Then, before the fluid was removed through the scleral incision, the suture was tied.

A large sarcoma causing a retinal detachment is easily revealed by its shadow, but a small tumor is not always easy to diagnose. However, a direct trans scleral transillumination is helpful, particularly when used with the ophthalmoscope. A small tumor reveals a shadow with this method. An excellent procedure is done with the slit lamp, with a flat Koeppe contact glass, by which it can be determined whether the elevated retina is translucent.

J. WOODHULL OVERTON, M D

Use of Roentgen Therapy for Retinal Diseases Characterized by New-Formed Blood Vessels (Eales' Disease, Retinitis Proliferans) A Preliminary Report JACK S. GUYTON and ALGERNON B. REESE *Arch. Ophthalmol.*, Chic., 1948, 40: 389

Over a period of 18 months prior to this report, a total of 22 eyes in 14 patients were treated by intensive roentgen therapy to the posterior ocular segment for certain ocular diseases. These diseases were characterized by retinal and vitreous hemorrhages with secondary fibrous tissue formation and new-formed blood vessels extending into the vitreous (Eales' disease, typical or atypical, and diabetic retinitis proliferans).

The irradiation technique was the same as that devised by Martin and Reese for the treatment of retinoblastoma. In the original cases from 8,000 to 10,000 roentgens (in air) were given through the temporal portal, and from 5,000 to 6,000 roentgens were given through the nasal portal, however, in later cases, a total between 3,500 and 6,000 roentgens were given only through the temporal portal. If the total dose did not exceed 6,000 roentgens, the patients could tolerate 500 roentgens three times a week through the temporal portal alone, which shortened the treatment time.

The first and most striking effect of roentgen therapy was the diminution of the new-formed vessels. The smaller vessels began shrinking within 2 or 3 weeks after therapy was begun and invariably disappeared from ophthalmoscopic view within 4 to 8 weeks, even if the total dose was only 3,500 roentgens. If a dose of not more than 4,000 roentgens was given, the larger new-formed vessels usually showed a shrinkage in caliber but remained patent

indefinitely. However, in eyes which received a total dose of 10,000 roentgens, or more, even the largest new-formed vessels completely disappeared from ophthalmoscopic observation. There has as yet been no definite recurrence of new-formed vessels in any of the 22 eyes treated. Regression of the fibrosis was less striking. If fibrosis was scanty, almost translucent, a dose of 10,000 roentgens or more produced a marked regression of the fibrous tissue. If fibrosis was dense and of long duration, it was reduced only slightly, even with heavy dosage.

In 8 patients with "typical" Eales' disease, there has been only 1 recurrent hemorrhage. In the group of 4 patients with "atypical" Eales' disease, there has been a recurrent hemorrhage only in 1 patient with an anomalous localized constriction of a retinal vein. In the 2 patients with diabetic retinitis proliferans, fresh retinal hemorrhages have continued to appear, and in 1 patient, fresh vitreous hemorrhages developed 5 months after therapy, even though the new-formed vessels were markedly diminished. It seems unlikely that roentgen therapy could result in permanent benefit for patients in this category until an effective treatment for diabetic retinopathy itself has been discovered.

MICHEL LOUTFALLAH, M D

Retinoblastoma (Retinal Glioma) Cured by Radon Seeds: Report of a Case JOSEPH WALDMAN and C. E. G. SHANNON *Arch. Ophthalmol.*, Chic., 1949, 41: 32

The authors report a case of retinoblastoma in which the left eye was enucleated and the right eye treated with radon seeds. Seeds were placed in an applicator devised by one of the authors, and sutured to the sclera under the conjunctiva and Tenon's capsule.

The authors arrived at the following conclusions:

- 1 Unilateral involvement requires immediate enucleation.
- 2 In bilateral involvement the more diseased eye should be enucleated and the other eye should be irradiated.
- 3 Radon should be used as described in this article, i.e., according to the technique of Martin and Reese.

EARL H. MERZ, M D

The Treatment of Bilateral Retinoblastoma ALGERNON B. REESE, GEORGE R. MERRIAM, JR., and HAYES E. MARTIN *Am. J. Ophthalmol.*, 1949, 32: 175

Since 1933 Reese and Martin have practiced the combined method of treatment for bilateral retinoblastoma. This consists of the surgical removal of the eye with the more advanced lesion and the treatment by fractionated roentgen irradiation of the remaining eye. Of 53 patients in the series, 25 are living with vision of 20/20 to 20/200, 16 are living without vision, and 12 have died of retinoblastoma. The average mortality of bilateral retinoblastoma treated by enucleation only is about 50 per cent. The combined treatment certainly does not adversely affect the chance of survival. The involvement of the two eyes is the result of independent origins of

quently suffered with polyarthritis, abortions, tumor, or diabetes. The patients themselves often had endocrine disturbances and other congenital defects. In the group studied there were 4 patients with luxation of the hip, 1 patient with congenital aplasia of an ear, and another with an imperfectly developed limb.

In most instances, before ankylosis manifests itself, the parents notice the lower jaw to be small, asymmetry of the face, faulty occlusion, and difficulty in widely opening the mouth. When examined the patients usually had brachycephalic head measurements, micrognathia, faulty dentition, and inability to open the mouth. Roentgen examination revealed underdevelopment of one or all of the bony structures in the region of the joint. The author considers both the prophylactic and the definitive treatment to be far less than desired. He advises general supportive therapy, such as vitamins, endocrines, adenoidectomy, and indicated orthodontal treatment, as soon as the premonitory signs are observed. Radical surgical interference, including bone grafts, insertion of metal prostheses, and manipulation, usually becomes necessary in the advanced cases.

N CHRISTIAN MEYER, M D

Cancer of the Tongue JAMES ENGLISH *Oral Surg., W. Path., 1949, 2: 231*

Cancer of the tongue is most commonly of epithelial origin and may result from chronic irritation. Lack of vitamin B should not be overlooked as a related causal factor. Frequently, if not always, certain premalignant states precede the cancerous lesion. These include leucoplakia, ulceration, and induration. The fact that pain is often not an early symptom may delay detection of the tumor. The importance of early diagnosis is emphasized because the prognosis is very grave after metastasis has occurred. Metastatic spread is by way of the lymphatic system and primarily involves the deep cervical chain of lymph nodes. The submaxillary and submental lymph nodes are frequently involved. The most successful method of treatment has been that of radium implantation in the primary lesion and complete surgical removal of the lymph nodes draining the affected side. Adjunctive roentgen therapy is frequently advocated.

Two cases of squamous cell carcinoma of the tongue are reported which illustrate several factors described in the review. The first patient was treated by roentgentherapy and radium, and the primary lesion regressed satisfactorily without recurrence, but subsequent lymphatic involvement occurred. Roentgentherapy was administered and repeated several times over a period of 31 months, when the patient died of an acute monocytic leukemia. The second patient had been treated previously with roentgen rays and radium. There was recurrence locally, so the primary lesion was treated by surgical removal of two-thirds of the tongue. Metastases to the cervical lymph nodes followed 2½ months later and were treated by radical neck dis-

section. The patient succumbed shortly thereafter to a flare-up of an old tuberculosis with massive involvement of both lungs, liver, spleen, and kidneys by acute tuberculous processes.

LOUIS T. BYARS, M D

PHARYNX

Prognostic Criteria and Therapeutic Suggestions for the Treatment of Tumors of the Pharynx (Il criterio prognostico e l'indirizzo terapeutico nel trattamento dei tumori della faringe) GIOVANNI PALTRINIERI *Radiol. med., Milano 1948, 34: 779*

The prognosis of tumors of the pharynx is based on correlation between histologic findings and radio sensitivity, also between radiosensitivity and curability, and especially with regard to epitheliomas. Other criteria, namely, anatomoclinical and radio clinical factors, represent important items.

Epitheliomas of mucous type are more radiosensitive than highly differentiated cancers. Not only the histologic structure, but the site of their origin determines the response of epitheliomas to irradiation. Those located in the pyriform fossa or at the base of the tongue show a poorer response than those of the tonsils or the tonsillar pillars.

Roentgenographic studies of the base of the skull are important in the prognosis, for they may demonstrate an invasion which escaped clinical detection. Such studies are valuable not only in patients with tumors of the nasopharynx but also in those with neoplasms of the mesopharynx and hypopharynx. Epitheliomas of the upper portion of the hypopharynx respond well to radiotherapy while those of the lower portion give a very bad prognosis.

The anatomoclinical findings, in addition to the results of histologic studies, determine the prognosis. For instance, vegetating forms without deep infiltration are amenable to cure while so called interstitial forms, with a deep infiltration, give a poor prognosis.

Angioreticulomas and lymphangioreticulomas are relatively radioresistant while reticuloendotheliomas and their polymorphous variety are sensitive to irradiation. The author discusses the merits of fractional irradiations over short and prolonged periods of time. He advocates the use of electrocoagulation in the treatment of circumscribed epitheliomas accessible to direct or indirect endoscopy.

NECK

Foreign Body in the Thyroid Following Perforation of the Esophagus EDWARD J. JIMPEL and JACOB S. ALTOFF *Surg., 1949, 5: 52*

Three instances in which an unusual sequence of events followed perforation of the esophagus by a foreign body have been encountered at the Mount Sinai Hospital, in New York, since 1931. In all 3 cases clinical and roentgenographic evidence of cervical and retroesophageal infection developed and external cervical drainage was performed. The first

ings, however, were at variance with the predominantly retroesophageal or paraesophageal infection that is usually found. Instead, the infection was chiefly confined within one of the lateral lobes of the thyroid gland, embedded within which was also found the foreign body. The perforation had apparently taken place more or less directly into the lateral thyroid lobe. Study of the literature has revealed no similar cases.

Perforation occurs also in a lateral, or even anterolateral, direction although this seems less likely when an instrument is the agent than in the case of a foreign body. In such an instance the foreign body can make its way directly into the corresponding lateral lobe of the thyroid gland. Conceivably, even a foreign body perforating posterolaterally might find its way into the thyroid gland if its course after perforation was lateral or anterolateral. This is what probably occurred in Case 1 in which a posteriorly situated perforation was seen endoscopically, although this might have represented instead a secondary evacuation site of the undrained retroesophageal abscess.

The infection which follows develops not only paraesophageally, but in the thyroid lobe as well. If the course has been directly into the thyroid with minimal traversal of the retroesophageal space, the infection may be entirely or chiefly within the gland. In Case 1, the infection was chiefly within the gland, only a small retroesophageal component being found at the secondary operation. In Case 2 the infection was confined entirely to the gland, at operation only edema was found in the retroesophageal space. In Case 3 the abscess cavity was both paraesophageal and intraglandular.

Characteristically, the infection should be anerobic with putrid odor, and liquefaction with abscess formation should be the rule. Phlegmonous extension should occur if drainage is too long delayed, but apparently this is more characteristic of perforation into the retroesophageal plane than when the dense confines of the thyroid have been penetrated. An abscess was the pathologic lesion in all 3 of the authors' cases, the infection was putrid in 2, and odorless in 1 case (Case 2).

In all 3 cases the foreign body was found entirely within the thyroid gland. Whether the initial vis a tergo carried it there, or whether the subsequent swallowing and gagging movements did, cannot be said. It should be noted that an edentulous, plated upper jaw probably predisposes to the ingestion of foreign bodies since the customary discriminatory sensation is eliminated from this area. This was mentioned by Myerson. Two of the patients wore upper plates, in the case of the third patient, no record was made although, in view of the patient's age, it is likely that she also did.

The diagnosis of esophageal perforation with paraesophageal infection is not difficult. A history of the ingestion of a foreign body, followed by neck pain, dysphagia, and fever is usually obtained. The physical signs are those of an inflammatory process

in the neck consisting of tenderness, mass, and fixation or displacement of the trachea. With perforation into the thyroid, the swelling and tenderness may be largely confined to the corresponding lateral thyroid lobe, which may suggest the specific diagnosis, as in Case 3. Esophagoscopy may be of assistance in demonstrating that a perforation has occurred. A lateral roentgenogram of the neck is indispensable. This will usually show the foreign body and air trapped in a widened retrotracheal space. The frontal film may show lateral tracheal displacement. Apparently there is not as great a tendency in these cases for infection to travel down the retrovisceral compartment into the superior mediastinum as when perforation has taken place into that compartment. This is manifested by tapering of the retrotracheal widening in the direction of the superior thoracic aperture.

Treatment consists of the establishment of external drainage through the neck and removal of the foreign body. The operation should be performed under local anesthesia. The technique, patterned after Marschik, is now well standardized. It is described in detail in Neuhof and Jernin's monograph. There should be no mortality. Chemotherapy will not substitute for surgery, and has a place only after adequate drainage has been effected.

It is important to retrieve the foreign body during the procedure as otherwise relief may prove to be only temporary, as in Case 1. Unless a definite search is made with the finger within the cavity in the thyroid gland, the foreign body may be missed as its location makes it difficult or impossible to bring it into the field of vision. The experience in Case 1 was instrumental in guiding the search in Cases 2 and 3 into the cavity in the thyroid gland where the foreign body was located.

JOHN E. KIRKPATRICK, M.D.

Observations on Disorders of the Thyroid Gland Associated with Exposure of the Suprarenal Glands to X-Rays. KLAUS A. J. JÄRVINEN. *Ann med int fenn*, 1948, 37: 227.

As a rule, a continuous correlation can be observed in the activity of the endocrine glands. Especially, the hypophysis has been found to exert a marked action on the function of the thyroid gland. The author observed 23 patients whose suprarenal glands had been exposed to roentgen rays.

As samples of the intimate relation of the thyroid to the sexual glands, the author mentions (1) enlargement of the thyroid gland during puberty and in connection with menstruation, (2) the frequent appearance of goiter during pregnancy, and dysfunctions of the thyroid gland subsequent to it, and (3) disturbances of thyroid secretion frequently observed in connection with the menopause.

Three patients developed strong symptoms, and 4 developed slight symptoms of hyperthyroidism. Ten others exhibited symptoms of hyperthyroidism, but owing to insufficient data (death of the patient) or other difficulties, these cases were not fully con-

clusive. In all of the patients with symptoms of hyperthyroidism, including the 10 doubtful cases, these symptoms appeared in from 1 to 3 months following roentgen therapy of the suprarenal glands. These symptoms receded spontaneously and partly disappeared in from one-half year to 3 years.

In 6 patients it was not possible to demonstrate any symptoms of hyperthyroidism following roentgen therapy applied to the suprarenal glands.

The author believes that a causal correlation exists between the roentgen therapy applied to the suprarenal glands and the symptoms of hyperthyroidism which subsequently developed in several cases.

From the author's investigations, it appears that treatment of the suprarenal glands by x-rays was, in several cases, the cause of a rapidly developing hyperthyroidism typical of Basedow's disease.

It is known that Basedow's disease frequently develops following tonsillitis, pneumonia, diphtheria, or influenza. On the other hand, the author believes that disturbances of the suprarenal glands may occur as a result of these diseases.

Furthermore, it must be remembered that hypoplasia of the suprarenal glands is most commonly observed in severe forms of Basedow's disease.

This view is also supported by the close similarity of morbus Basedowi to Addison's disease. The following features are mentioned as common to both: loss in weight, myasthenia, intestinal disorders, increased pigmentation, loss of hair, atrophy of the sexual glands, hyperplasia of the thymus and of lymphatic tissue, liver disorders, and mental disturbances.

There are circumstances which would seem to indicate that suprarenal lesions may have a greater significance as an etiologic factor in Basedow's disease than is generally ascribed to them.

Among other observations made during this investigation, the author mentions the effect of roentgen treatment of the suprarenal glands on blood pressure, noting a rise. In one case of diabetes mellitus the blood sugar, and particularly the amount of sugar excreted in the urine, decreased considerably

after exposure of the suprarenal glands to roentgen rays.

GEORGE W. RICHARDSON, M.D.

The Surgical Treatment of Thyrotoxicosis. K. PATERSON BROWN. *Edinburgh M J*, 1948 55: 265.

The operative treatment of hyperthyroidism in Edinburgh hit a low point in 1943 when thiouracil was introduced but since then it has risen again. Thyroidectomy is indicated in primary hyperthyroidism when thiouracil fails to control the symptoms, in complications resulting from drug treatment, when thiouracil causes excessive gland enlargement, if the patient wishes the operation, and in nonco-operative patients. In secondary toxic goiter, surgical measures give better results, as in recurrent goiter and in substernal goiter, in which thiouracil seems contraindicated. Persistent cardiovascular complications are more rare after operation. Malignant degeneration of a nodular goiter is not uncommon, and there is a theoretical question whether it may not occur after thiouracil treatment. Cardiac patients seem to feel better following thyroidectomy than after medical measures alone. Recurrent goiters should be treated by drugs rather than by a second operation, unless drugs fail. The author charts the pulse rate every 5 minutes and believes that the pulse curve gives a better indication of the patient's condition than the absolute pulse level during operation.

Brown uses thiouracil in the preparation of the patient, thus he discontinues 12 days before the operation and gives iodine as a substitute. During the operation he uses an oxidized cellulose gauze for the control of oozing. Tetany is a rare complication, bilateral recurrent nerve injury has not occurred. Of 3 patients with unilateral injuries 2 had completely recovered, but the third had not recovered completely at the time of writing. Late bleeding occurs rarely and must be controlled by prompt intervention. There was no mortality in this series, but the over all mortality in all types of cases was 1.6 per cent.

F. W. S. MODERN, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS, CRANIAL NERVES

The Diagnosis of Focal Epilepsy (Diagnóstico da epilepsia focal) DJALMA CHASTINET *Rev brasil cir*, 1948, 17 733

The concept of focal epilepsy is purely objective it is based on the demonstration of an area in the central nervous system, a focus, in which originate the periodic neuronal discharges that characterize the clinical attack of the disease. The epileptogenic focus has no autonomous existence, it always arises in connection with a neighboring lesion which is the epileptogenic lesion. This may be a structural change in the nervous substance, such as a cerebral scar or an encephalic tumor, or it may act indirectly on the cerebral tissue as in the case of extradural and subdural hematoma, tumor of the dura mater, or localized hyperostosis of the skull. No matter what it is, the epileptogenic lesion in itself cannot induce an epileptic attack because its tissue is electrically and biologically inactive. However, this is not the case with the neighboring nervous tissue whose neurons are functionally active and subjected to irritation by the lesion, they are stimulated to hyperactivity and become the epileptogenic focus. Both lesion and focus are indispensable etiopathogenic elements of focal epilepsy, the lesion is the primary determining cause, and the focus is its neighborhood reflex.

The diagnosis of focal epilepsy includes the clinical study of the attack, the topographic study of the lesion, and electroencephalography, completed by the operative diagnosis which requires cortical stimulation tests and electrocorticography. For the clinical study of the attack the patient often has to be hospitalized. When the observed symptoms allow the epileptic manifestation to be referred to a certain cerebral area, the diagnosis of focal epilepsy may be safely made, but when the epileptic attack presents no signs of focus, the hypothesis of focal epilepsy should not therefore be rejected. Focal epilepsy may be expressed also by generalized attacks without any sign or symptom of localization. The topographic study of the lesion indicates only indirectly the location of the focus which is in the vicinity of the lesion.

Cortical stimulation, which is based on the provoked repetition of the initial phenomena of the clinical attack, presents the same diagnostic difficulties as the clinical study of the attack. It is necessary to conduct a very complete observation of the beginning of the clinical attack in its smallest details to be able to estimate with certainty the localizing value of the answers received from the stimulation. Electroencephalographic examination may be performed in the ambulant patient, it causes no disturbance, may be repeated as many times as found necessary, and, like electrocorticography which is a

variant of it, is highly efficient and allows exact localization of the epileptogenic focus.

In conclusion, electroencephalographic examination is the method of choice for the diagnosis of focal epilepsy, in this as in the other modalities of epilepsy, its value is superior to that of any other procedure and can be summarized in its principal advantages: convenience, innocuity, efficacy, and precision. However, the author does not mean to exclude other examination methods in order to arrive at the diagnosis.

RICHARD KEMEL, M D

Gangrene of the Face Following Occlusion of the Posterior Inferior Cerebellar Artery NATHAN SAVITSKY and SIDNEY P. ELPERN *Arch Neurol Psychiat*, Chic, 1948, 60 388

The authors point out that skin lesions following disease of the trigeminal nerve have rarely been reported. The majority of such skin lesions follow surgical section of the nerve, and are characterized by temporary herpetic lesions.

A case is reported with occlusion of the posterior inferior cerebellar artery and associated hypalgesia on the left side of the face. The patient subsequently developed an ulceration of the ala of the nose, and a progressive deep ulceration involving part of the nose and cheek, which was entirely painless. There was no evidence of any syphilitic lesion.

The rarity of such trophic lesions is pointed out, and the possibility of trauma as an etiological factor is discussed.

HOWARD A. BROWN, M D

The Absence of Headaches in Certain Types of Frontal Lobe Tumors (Pourquoi certaines tumeurs frontales évoluent-elles sans céphalées) J-A CHAVANY and E. WORINGER. *Presse med*, 1948, 62 738

In reviewing their cases of intracranial tumors, the authors noticed that headaches were not always present in patients who had frontal lobe tumors. They then analyzed the symptoms presented by 137 proved cases of tumors restricted to the frontal lobes and accompanied by papilledema, and found that 26, or 19 per cent of them, had not been accompanied by headaches. Most of the patients without headaches presented the psychic disturbances grouped under the name of frontal lobe syndrome. There appeared to be a direct relationship between the psychic disturbances and the headaches in the clinical course of these patients. Thus, when the disease started with frontal lobe symptoms it would often not be accompanied by headaches, or the headaches would disappear with the onset of psychic symptoms, at times these two symptoms would alternate but not be present simultaneously. Headaches were present in 61.4 per cent of the patients without psychic disturbances and in only 8.9 per cent of those with frontal lobe symptoms, while 22.3 per

cent of patients with frontal lobe tumors and only 4.3 per cent of the nonpsychotic patients had no headaches.

The authors believe that the absence or recession of pain is caused by an anatomical or functional interruption of the thalamofrontal pathways and that in certain cases the frontal lobe tumors produce the same effect as a prefrontal lobotomy.

GEORGE PERRET, M D

Giant Adenomas of the Hypophysis, Considerations on 2 Cases (Adenomas gigantes da hipófise—considerações sobre dois casos) CANDIDO DE OLIVEIRA *Rev brasil cir*, 1948, 17 721

Adenomas occur frequently in the hypophysis. Their classification depends on their cellular composition which causes a characteristic symptomatology: acidophil cell tumors are responsible for gigantism and acromegaly, chromophobe cell tumors for infantilism or adiposogenital dystrophy, and basophil cell tumors for Cushing's syndrome. In general, the tumors are grayish red, well vascularized, and of varying size. They may grow slowly or rapidly, and be endosellar, suprasellar, or infrasellar. When endosellar, the tumor remains for a long time in the sella, then, because of constant pressure by the tumoral mass, the sella is destroyed and the tumor may grow upward in the direction of the hypothalamic region, compressing the floor of the third ventricle and the optic chiasma, or backward in the direction of the cerebellum and the cerebral peduncles, it may even reach the corpus callosum, the lateral ventricles, and the frontal and temporal lobes. There is no direct relationship between the size of the tumor and its endocrine activity. The basophil cell adenoma is the least common of the three types of tumor.

In a study of large tumors of the hypophysis, Carrillo found that, after a prolonged local phase, the tumor destroys the framework of the sella, grows rapidly, and causes clinical symptoms which simulate those of cerebral and not hypophyseal tumor. This has been confirmed by White and Warren who stated that the clinical diagnosis then becomes so difficult that surgeons have been led to intervene in zones remote from the primary tumor. Another characteristic of these large tumors is their mortality in connection with some operation: death may occur suddenly after or during a simple lumbar or ventricular puncture and even in the course of a decompression operation. Carrillo and Ghersi have called attention to the fact that acidophil adenoma in the terminal phase of acromegaly may become voluminous through adenocarcinomatous degeneration. Ghersi has found that the prognosis of large tumors of the hypophysis is usually favorable when their growth is toward the frontal region, uncertain when it is toward the third ventricle, and grave when it is toward the posterior fossa, compressing the protuberance and the bulb.

Chromophobe adenomas are the hypophyseal tumors which most frequently reach a considerable

size. In their growth they cause clinical symptoms which have nothing to do with the histologic nature of their cells but which result from compression and destruction. Even when small, these tumors which do not secrete hormones destroy the secreting cells, and thereby cause glandular hyposecretion which results in amenorrhea in the female and impotence in the male, dry skin, and low basal metabolism.

The author reports 2 cases of giant tumor of the hypophysis: one of chromophobe adenoma with Simmond's syndrome, the other of acidophil adenoma with acromegaly. Neither patient presented the deceptive symptomatology mentioned by Carrillo, White, and Warren. The tumors weighed 77 and 146 gm, respectively, and it is interesting to note that the chromophobe adenoma, which easily attains a considerable size, was smaller than the acidophil adenoma, which generally remains small. In addition, the great volume of the chromophobe adenoma was not due to malignant degeneration. Morphologic examination of the 2 tumors revealed hemorrhagic foci distending the mass and demonstrating the direct cause of death of the 2 patients.

RICHARD KEMEL, M D

Frontonasal Encephalomeningocele Corrected by Meningeal and Bony Plastic Procedure (Un céphaloméningocèle frontonasale guérie par plastic méningée et osseuse) G. LAZORTHES, F. DEODATI, and P. FAGE *Presse méd*, 1949, 59 3

The authors have previously reviewed the various types of encephalomeningoceles and have discussed briefly the pathogenesis of this cranial deformity which they believe is due to a simple agenesis of the bone at certain predominant suture lines. They note that it is commonest at the lambda and bregma, but from reports of other authors it occurs also in the parietal, nasal, nasopharyngeal, and orbital regions.

They report in some detail their own experience with a 2 year old child who had a progressively increasing lesion of the soft tissues between the eyes over the base of the nose, due to an encephalomeningocele through the anterior ethmoidal region, with a defect in the frontal bone in the midline and at its junction with the nasal bones. Through a bifrontal osteoplastic flap, they found the right frontal pole herniated out into the subcutaneous levels. The contained brain, broadly pediculated, was transected and left in place so as not to open the nasal fossae into the intracranial spaces. The dura mater was closed with amniotic membrane and the bony defect closed by a 5 cm. long piece of rib removed from the child's mother. This bone was placed below in the ethmoidal plate. Recovery was prompt and rapid with a general improvement in the patient's condition.

JOHN MARTIN, M D

Glossopharyngeal Neuralgia—Extracranial Neurectomy JOHN T. MORRISON *Brit J Surg*, 1945 36 208

Theoretically, extracranial avulsion of the ninth nerve should give merely transient relief of glossop

pharyngeal neuralgia, whereas intracranial preganglionic section of the nerve affords permanent relief. The author cites the cases of 2 patients of his colleague, Professor Herbert Williams, who had termination of pain for 8 and 10 years respectively after performance of the former procedure. For this reason, and the fact that most individuals suffering from this malady are quite elderly, the extracranial approach is believed worthy of consideration.

The incision is started behind the mastoid process and curved forward toward the hyoid bone with a slight convexity downward. A partial section of the sternocleidomastoid muscle may be performed with exposure of the spinal accessory nerve. The posterior belly of the digastric muscle and the external carotid artery, which lies deep to it, are retracted forward and upward. The styloid process may be palpated posteriorly, and, if long, may be cracked to enable better exposure. Upward traction on the digastric muscle and nearby structures may cause pressure on the lowest branch of the seventh nerve with occasional temporary paresis.

The spinal accessory nerve should be traced over the internal jugular vein to the point at which it disappears into a well defined fascial layer, an upward prolongation of the carotid sheath which is firmly attached to the outer edge of the jugular foramen. Incision of the fascia over the nerve leads one directly to the jugular foramen where the ninth, tenth, and eleventh nerves emerge. For better exposure it is occasionally necessary to divide the small inferior petrosal sinus where it joins the internal jugular vein, about an inch below the foramen. The glossopharyngeal is the smallest and most anterior nerve running forward across the internal carotid artery. It is grasped with a forceps, divided, and avulsed proximally by continuous traction. Avulsion of the nerve causes anesthesia of the tonsil, fauces, and posterior portion of the tongue, and some interference with the swallowing reflex.

The author cites a case in which this procedure was performed on a 66 year old white female. On the day after operation she had severe pain in the neighborhood of the ear, which was believed to be due to central stimulation of the area from which the nerve was torn. Likewise there was trivial discomfort felt in front of and behind the ear for a few days, but this gradually diminished. It was thought that these symptoms were probably due to stimulation of the auricular branch of the vagus which connects with the petrous ganglion. Since approximately an inch of nerve was avulsed from the jugular foramen it is difficult to see how this could be done without likewise avulsing the jugular and petrous ganglia which lie in and just above the foramen. Thus the author believes that this type of avulsion actually causes preganglionic section of the fibers, and is most likely the reason for the prolonged relief of the neuralgia.

RICHARD C SCHNEIDER, M D

SPINAL CORD AND ITS COVERINGS

Tumors of the Spinal Cord R N COOPER *Ind J Surg*, 1948, 10 321

The author reviews the principles of diagnosis of spinal cord tumors, including clinical, mechanical, chemical, and roentgen ray methods.

A classification of tumors of the spinal cord is presented, and the treatment and prognosis are discussed.

HOWARD A BROWN, M D

The End Results of Operations for Intrathecal Extramedullary Spinal Tumors, with a Report of 9 Patients Whose Tumors were Removed 14 to 22 Years Previously LAMBERT ROGERS *Austral N Zealand J Surg*, 1948, 18 119

The author presents a follow-up study on 9 patients who had been operated upon for intrathecal extramedullary spinal tumors 14 to 22 years previously. Six of the group had meningiomas and 3 had neurinomas. In none of the group was there recurrence of the tumor, but it was necessary to reoperate upon one of these patients because of pain from intercostal neuralgia. At operation this patient was found to have arachnoiditis. After separation of adhesions there was relief of the symptoms.

It is concluded that the outlook is good if pressure from these tumors has not compressed the cord beyond the point of recovery of its conduction. From various recorded series, it would seem that results following the removal of spinal neurinomas are particularly favorable, whereas results following the removal of meningiomas are less satisfactory because of the danger of recurrence, or the occurrence of local arachnoiditis at the operative site. To prevent these complications it is advisable to excise a sufficient area of dura mater at the base of the meningioma.

RICHARD C SCHNEIDER, M D

Considerations Based on a Statistical Study of Spinal Cord Surgery, 113 Observations (Réflexions sur une statistique de chirurgie médullaire 113 observations) PIERRE WERTHEIMER and SAUTOT *Rev chir*, Par, 1948, 67 321

The authors review 113 operations for spinal cord disease, not including cordotomies, myelotomies, or rhizotomies. Their studies do not include surgery of the lumbosacral syndrome.

Nineteen of these patients had intramedullary tumors, 33 had intradural and extramedullary tumors, and 18 had extradural tumors. Twenty-two patients had recent or old spinal cord injuries such as wounds or contusions of the cord, traumatic arachnoiditis, compressions, and so forth. There were, in addition, 2 cases of syringomyelia, 1 case of hematomyelia, 7 cases of nontraumatic arachnoiditis, and 5 cases of acute or chronic subdural inflammatory lesions.

In this group there was a total mortality of 26 per cent up to several months after surgical intervention. The authors state that follow-up observation of the motor, sensory, sphincter, and trophic condition of patients after they have left the hospital is a very

difficult task and makes documentation of the results of spinal cord surgery very difficult in those very patients who do have the best operative results, since they live to leave the hospital and return to their normal surroundings

Obviously, the poorest results are in those patients who have glioma of the spinal cord, in whom the mortality rate was 40 per cent. The mortality rate was only 10 per cent for subdural tumors and 20 per cent for extradural lesions

The authors have found the generous use of whole blood very useful in the postoperative care of patients. They emphasize, particularly, that the earliest possible surgical intervention is important in patients with a surgical lesion of the spinal cord. Without doubt, the nature of the functional results does depend on the nature of the lesion, its anatomic site, the actual chance which its intrinsic nature offers for complete removal, the age of the person, and particularly the length of time which compression has been in effect. They have found that (in addition to a case history and the findings of lumbar puncture) lipiodol myelography has allowed earlier and more accurate diagnosis, thus leading to the desired earlier operation

JOHN MARTIN M D

PERIPHERAL NERVES

Electrodiagnosis of Lesions of Peripheral Nerves in Man LEWIS J POLLOCK, JAMES G GOLSETH, FRANK MAYFIELD, ALEX J ARIEFF, and Y T OESTER *Arch Neur Psychiat*, Chic, 1948, 60 1

The authors attempt to describe the characteristics of response of muscle to all stimuli studied, and to define a formula for normal, degenerative, denervated, regenerating, and recovered states of muscles

One-hundred per cent neurotization time is defined as the percentage or multiple based on a rate of regrowth of 5 mm a day

The authors continue to define galvanic, progressive, and faradic currents, and rheobase. They discuss galvanic anodal and cathodal opening and closing stimuli, as well as galvanic tetanus ratio, strength-duration currents, chronaxia, Pflueger's law, and the reaction of degeneration

Their conclusions concerning the characteristic response to various stimuli in the several states may be broadly summarized as follows

Normal Chronaxia a fraction of a millisecond, rheobase ratio greater than 1, tetanus ratio of 3.2 to 9.5, a continuous strength-duration curve, response to faradic stimuli, and slight facilitation

Denervation Chronaxia greater than 15 milliseconds, rheobase ratio of 1 or less, tetanus ratio of 1, continuous strength-duration curve, no response to faradic stimuli, and pronounced facilitation

Early degeneration A high tetanus ratio at a time before regeneration could have occurred, followed later by a tetanus ratio of 1

Early regeneration A high tetanus ratio, increase of rheobase and, occasionally, shortening of chronaxia

Maturation A chronaxia of 15 milliseconds or less, a high tetanus ratio, response to faradism, and a flat curve to repetitive stimuli

Partial lesion Chronaxia of less than 15 milliseconds, tetanus ratio of about 2 at a time less than 100 per cent neurotization, but after complete denervation should have occurred, a reaction to faradic stimulation and a flat strength-interval curve may likewise be noted

HOWARD A BROWN, M D

The Painful Sequelae of Injuries to Peripheral Nerves S SUNDERLAND and M KELLY *Austral N Zealand J Surg*, 1948, 18 75

The authors present an excellent review of painful symptoms following peripheral nerve injuries. A complete bibliography is appended

The various sources of pain in these injuries are listed. Causalgia is defined as severe pain in an extremity, which has persisted for at least 5 weeks after the receipt of injury to a nerve trunk. Examination of 339 peripheral nerve injuries in 301 patients revealed that only 34 patients, all of whom had sustained war injuries, met the criteria of causalgia after the exclusion of all doubtful cases. The case histories of all these individuals are given in detail. The periods of follow-up ranged from 2 to 5 years

The clinical features of the pain are described. The quality of the pain is evaluated and an attempt is made to determine what influence physical measures played in its relief. In all cases the pain was noted in the hand or foot and involved the distribution of the injured nerve. When the causalgia accompanied complete interruption of conduction it was referred to the denervated area. It is pointed out that areas of returning sensation are hyperalgesic, but in causalgic individuals the pain is of a greater degree, more persistent, and covers a much greater area than that of the injured nerve. In most individuals the onset of pain was shortly after injury, within 24 hours to a week. The pain could be increased by any increase in activity of the limb or any stimulation of activity of the central nervous system. In about half the patients the causalgia became bearable in 4 or 5 months, while most of the remaining patients lost their discomfort in a year

In a large majority of the patients with causalgia there was involvement of the brachial plexus, sciatic nerve, and median nerve. Their susceptibility to this type of pain is due to the fact that these trunks carry the bulk of sensory and sympathetic fibers to the limbs. The relationship of causalgia to the site of injury, the type of wound, the etiologic agent, trophic changes, injuries to associated tissues, and the psychogenic component are all reviewed. The indications of sympathetic involvement, such as sweating and flushing of the extremities, and the results following sympathectomy are described completely

Anatomical and physiological concepts are presented, with special reference to the pain pathways and the presumed alterations in them caused by

injury The effects of injury to the cell body, neuron, and the central nervous system are discussed, and the importance of antidromic conduction is emphasized

The results of surgical treatment are tabulated under the headings of nerve block, neurolysis, neurotomy, amputation, posterior rhizotomy, chordotomy, ablation of the sensory cortex, and sympathectomy. It is speculated that the success of the last procedure is due to a modification of the disordered pattern of internuncial neuronal activity in the spinal cord

Inasmuch as most cases of causalgia undergo spontaneous cure, the authors believe that surgery should be reserved for the stubbornly persistent cases, and that preganglionic sympathectomy is definitely the procedure of choice if operation is undertaken

RICHARD C SCHNEIDER, M D

Experimental and Anatomosurgical Study of Anastomosis of Phrenic and Recurrent Nerves for Treatment of Traumatic Lesions of the Inferior Laryngeal Nerve (*Ricerche sperimentali ed anatomochirurgiche sulla anastomosi frenicoconcorrente nella terapia delle lesioni traumatiche del nervo laringeo inferiore*) RENZO VERNETTI *Arch ital chir*, 1948, 70 363

An end-to-end anastomosis of the proximal end of the phrenic and the distal end of the recurrent nerve was performed by the author on 5 dogs. In 2 dogs the anastomosis was performed immediately following a trauma of the inferior laryngeal nerve—in 1 dog 20 days, in 1 dog 40 days, and in 1 dog 60 days after such injury. After the anastomosis, the paresis and atrophy of the vocal cord disappeared in all animals and the mobility of the corresponding side of the larynx was restored. A complete restitution of movements of the vocal cord and the hemicartilage

took place within 52 to 72 days after the anastomosis. Studies on cadavers convinced the author that this procedure may be employed in man without danger and without great technical difficulties

JOSEPH K. NARAT, M D

Personal Experiences with the Surgical Treatment of Essential Hypertension (*Über die chirurgische Behandlung der essentiellen Hypertonie auf Grund eigener Erfahrungen*) W. BRUNNER *Helvet chir acta*, 1948, 15 307

The author presents 10 cases of hypertension in patients who were operated upon at the Zurich University Clinics. Supradiaphragmatic sympathectomy with splanchnicectomy was performed in 6 cases and thoracolumbar sympathectomy with splanchnicectomy in 4 cases. In this group of patients, who were between the ages of 41 and 65, there were 2 with nephrosclerosis, 2 with cardiac insufficiency, and 1 patient who had had two apoplectic attacks. Four of the patients who underwent supradiaphragmatic sympathectomy had a recurrence of their hypertension and associated symptoms within 8 months after operation. Those who had thoracolumbar sympathectomies showed better and more permanent results.

The results depend to a large extent on the anatomical changes that have taken place in the peripheral vessels, on the presence of hypertonic substances in the blood, and on the degree of the heart and kidney damage. Good results were obtained in the patients who responded preoperatively with a drop in blood pressure from paravertebral or splanchnic blocks or reacted to the sympathicolytic drug, dibenamin. Age, old encephalopathy, or cardiac enlargement were not considered as contraindications for the surgical treatment of malignant hypertension.

GEORGE PERRET, M D

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Plasma-Cell Mastitis MAX CUTLER. *Brit M J*, 1949, 1 94

Since plasma-cell mastitis was first described by Cutler and Cheate in 1931, fewer than 50 cases have been reported. Despite its rarity, its importance in the differential diagnosis of carcinoma of the breast warrants emphasis.

Plasma-cell mastitis has a sudden onset with pain, tenderness, and redness of the skin. It usually occurs in a nonlactating breast. At first the entire breast is swollen and there is painful axillary lymphadenopathy. Fever, sometimes accompanied by chills, is usually present. A creamy discharge from the nipple is not uncommon. The acute symptoms soon subside and the process enters the subacute stage. Here pain and tenderness have diminished and the swelling of the breast has decreased often leaving a diffuse nodularity. When all acute and subacute signs of inflammation have ceased there remains a discrete, hard, solid, residual mass with attachment to the overlying skin. Nipple retraction may exist. The axillary nodes are enlarged and firm. The breast presents the classical signs of carcinoma and it is only by eliciting the history of the previous inflammatory episode that the correct diagnosis can be established and the patient saved from a radical mastectomy.

Grossly the breast involved by plasma-cell mastitis reveals numerous dilated ducts and minute cysts which under pressure exude thick, creamy material. The fibrous and epithelial elements are indurated with radiating strands of dense, translucent, fibrous, connective tissue. In some portions there may be soft, semi-necrotic, gray areas, and xanthomatous foci. The induration and resistance of the tissue simulate carcinoma, but even in the most dense portions the classical cicatrices and chalky appearance characteristic of carcinoma are not present. In addition the process is diffuse and does not form a definable tumor.

When viewed microscopically, one sees an acute and subacute exudative inflammation with abundant lymphocytes, plasma cells, and leucocytes. The process is diffuse, involving both the glandular and the interstitial tissues. The exudate is particularly prominent about the ducts and acini where the cellular reaction may consist almost entirely of plasma cells. Foreign body giant cells may be encountered. Dilated ducts are filled with, and distended by, desquamated epithelial débris.

The diagnosis is comparatively simple if the patient is seen in the acute or subacute phases. Repeated examinations will determine whether the disease is progressing or regressing and this is the most important single factor in differential diagnosis. Plasma-cell mastitis must be differentiated from inflammatory carcinoma, diffuse duct carcinoma, and

traumatic mastitis. The initial stages of plasma-cell mastitis resemble those in inflammatory carcinoma, however, in the latter, carcinomatous invasion of the subdermal lymphatics gives rise to irregular, ridgelike thickening of the skin not present in plasma-cell mastitis. Diffuse duct carcinoma resembles plasma-cell mastitis, but it is steadily progressive while the other is steadily regressing. Traumatic mastitis is easily differentiated by its history of trauma.

There are two pitfalls in microscopic interpretation, and both apply especially to examination of frozen sections in which fixation is usually inadequate. The epithelial hyperplasia often appears to have invaded structures outside their normal boundaries. Plasma cells may be so large and edematous that they resemble anaplastic malignant epithelial cells. Clinical evidence does not support the idea that plasma-cell mastitis is a premalignant condition. The best treatment is biopsy and, after the diagnosis is established, local excision or simple mastectomy. Irradiation should be used during the acute and subacute stages, followed by surgery in the chronic phase.

A 37 year old woman told of having pain, for a period of two weeks, in the right nipple accompanied by swelling and tenderness of the right breast. Examination disclosed an enlarged breast with a firm, solid, movable mass about 8 cm in diameter attached to the overlying skin. Several enlarged movable lymph nodes were present in the axilla. The diagnosis of diffuse duct carcinoma was made and irradiation was prescribed because of the probability of inflammatory carcinoma. Several days after the completion of treatment rapid regression of the tumor began. This suggested the likelihood of plasma-cell mastitis, a diagnosis confirmed by biopsy. A simple mastectomy was performed.

Almost 7 years later the patient complained of pain, tenderness, and nodularity in the left breast recurring periodically at monthly intervals. Examination of the left breast revealed it to be enlarged, tender, and the seat of diffuse nodularity. A local excision was done 7 years after the onset of symptoms in the left breast. This is believed to be the only recorded instance of involvement of both breasts by plasma-cell mastitis.

C. FREDERICK KITTLE, M.D.

Multilocal Hematoma of the Mammary Gland
(Hématome mammaire à foyers multiples) R. ROUX, A. AMELINE, and P. GAUTHIER VILLARD. *Presse méd*, 1949, No 2 24

The author reports the case of a woman, 52 years of age, who, 2½ years after the menopause, suddenly experienced violent pains in the left breast during the night. After a few hours, blood extravasation appeared on the skin.

Examination revealed a mass at the superior medial quadrant. The blood picture was normal. The mass was excised, and histologic examination revealed numerous hemorrhages in the subcutaneous fat tissue. The pathogenesis of this condition remained unexplained. WERNER M. SOLMITZ, M.D.

Statistical Studies on the Role of Histology in the Postoperative Prognosis of Mammary Carcinoma (Précisions statistiques sur le rôle de l'histologie dans le pronostic post-opératoire du cancer du sein) G. GRICOUROFF, M. FAUTREL, J.-M. FAVERGE, and J. ARZUR. *Presse méd.*, 1949, 57: 118.

A series of 281 patients with mammary carcinoma who were subjected to operation was divided into four groups according to the degree of malignancy found on histological examination. The mortality rate 5 years after surgery was 25 per cent in degree 1, 50 per cent in degree 2, 66 per cent in degree 3, and 85 per cent in degree 4.

In order to prove that the differences between the four categories were not a matter of chance, and to show the dependability of prognoses based on histological studies, the authors analyzed the figures by means of modern mathematics (the asymptotic method of χ^2 and the exact method by calculus P).

The same methods were applied to the figures concerning the size of the tumors and the degree of lymph node invasion. WERNER M. SOLMITZ, M.D.

Edema of the Upper Extremity in Mammary Cancer (O edema do membro superior no cancro da mama) MARIA FERNANDA MARQUES and SUZANA CÉZAR. *Arg. pat.*, 1948, 20: 1.

In a statistical review of 3,491 cases of mammary carcinoma the authors found 275 cases of edema of the upper extremity. Of the 3,491 patients 1,592 were not operated upon, of the 1,899 remaining, 1,115 were operated upon on the service of the Portuguese Institute of Oncology and 784 elsewhere. Among the patients who were operated upon, there were 210 with edema, including 65 operated upon in the service and 145 operated upon elsewhere, the remaining 65 cases of edema occurred in the 1,592 patients who were not operated upon.

According to the present concepts concerning localized edema, the simple fact of obstruction of a vessel, even an important one, does not suffice to produce edema, and various factors relegate vascular obstruction to a secondary place. It seems that the changes in the central or peripheral, and, above all, in the vasomotor nervous system, and the endothelial changes must be conceded first place. Organic debility is perhaps an adjuvant factor of some importance.

It has been noted that the adenopathies which developed after operation were more often accompanied by edema than those which developed with the tumor although the latter were much larger than the former.

The authors report a number of cases. In some patients who were not operated upon, the appear-

ance of the edema coincided with the development of the glandular masses. Among the patients in whom the edema appeared without the presence of palpable glands following operation or not, there were some in whom there was no known or presumable cause for it, and others in whom the edema coincided with the cancerous lymphangitis of the skin of the mammary region after operation or of the breast itself, in the absence of operation. In contrast to the cases in which cutaneous lymphangitis seemed alone to be responsible for the edema, there were others in which lymphangitis associated with axillary and supraclavicular adenopathies had not caused edema.

At the Institute radium has been applied next to the axillary vein after operation since 1937, and this direct irradiation of the vessels without interposition of tissue or other protection except filtration has never caused edema. Roentgen therapy given in varying dosage and with various techniques has never had any influence on the appearance of edema, but has sometimes aided in its disappearance or reduction. Finally, the histologic examination of specimens obtained at operation has not led to any conclusion concerning the relationship between the kind of tumor and the frequency of edema.

From another point of view, a case is reported that shows the connection of edema with intercurrent erysipelas, while other types of intercurrent infection (ulcerated and infected lesions of the breast or axillary space) have not caused edema, and neither have other types of postoperative infection.

The authors believe that they cannot draw any conclusion from their review of this series of cases of edema of the upper extremity in mammary cancer. If in one case the etiology could seemingly be established on some fact or detail, another identical case soon occurred to prove the error of this assumption. RICHARD KEMEL, M.D.

Adenocarcinoma of the Axillary Lymph Nodes Without Demonstrable Breast Lesion (Adenocarcinoma en ganglio axilar sin lesión mamaria manifiesta) JUAN WESTERMEYER K. *Rev. méd. Chile*, 1948, 76: 617.

The author presents 6 cases (1 personal case and 5 cases collected from the experience of his colleagues) in which an axillary mass was the presenting complaint. Biopsy showed this mass to be a metastatic adenocarcinoma of axillary lymph nodes. No lesion could be detected in the corresponding breast. In one case a benign fibroadenoma was found in the opposite breast.

The 6 patients were women between 38 and 78 years of age. In 3 patients a primary breast lesion developed in from 3 to 20 months following observation of the axillary tumor, and a radical mastectomy was performed. The other 3 patients have gone 8 to 16 months without evidence of a breast lesion, but 2 of them have undergone irradiation.

Although various explanations for the occurrence of a metastatic axillary adenocarcinoma are pre-

sented, the assumption must be that the primary lesion lies in the corresponding breast, and it is believed that radical surgical treatment is in order at the time the axillary tumor is recognized if other tumors capable of producing axillary metastases can be reasonably well excluded

HIRAM T. LANGSTON, M D

The Influence of Pregnancy on Cancer of the Breast

BARNEY BROOKS and JAMES N. PROFFITT *Surgery*, 1949, 25, 1

The question of the influence of pregnancy on cancers of the breast arose because of serious questioning of the senior author's advice that there was no contraindication to pregnancy in a 35-year-old woman who had had a radical breast resection for cancer without metastasis. This questioning prompted a review of the literature and of the experience at the Vanderbilt University Hospital, Nashville, Tennessee, during the past 22 years concerning the effect of pregnancy on existing cancer of the breast, and the production of cancer in the second breast when one had been removed prior to the pregnancy.

From October 1, 1925, to January 1, 1948, 395 patients were operated upon for breast cancer in the Vanderbilt University Hospital. One hundred and twenty-three were less than 46 years of age and were arbitrarily considered to be in the child-bearing age, these were the subjects of this study. Seventy were operated upon more than 5 years previously and 44 less than 5 years previously.

The results following radical amputation on patients observed 5 or more years after operation are shown in Table I.

It is of passing interest that of all patients seen 80 per cent were operable and were subjected to radical mastectomy, and that of this group 40 had either gross or microscopic axillary metastases, while 23 patients had neither gross nor microscopic axillary metastasis.

Six patients, between 21 and 39 years of age, were either pregnant or lactating when the carcinoma was discovered (3 of each). Two had been subjected to radical mastectomy and 4 to simple mastectomy. All had gross axillary metastases. All but 1 of the patient were dead in less than 2 years, the 1 who is living and well has had a 15½ year cure (Geschickter, in 1945, stated that he could find no reported cure of cancer of the breast operated on during pregnancy).

TABLE I

	No of cases	Percentage apparently cured
Group 1. No axillary metastasis	22	73
Group 2. Microscopic metastases	4	50
Group 3. Gross axillary metastases (including 7 simple mastectomies)	41	22 (29% radical mastectomies)
Group 4. Distant metastases	6	0

Since 5 of these 6 patients died within 2 years following the operation, the belief that pregnancy promotes the rapidity of growth of existing mammary cancer is supported.

Five patients became pregnant after radical amputation of a breast for cancer, and these have been followed up from 9 months to 6 years. Four had no axillary metastases, the 1 patient with axillary metastasis died approximately 1 year following operation. None has developed primary or recurrent cancer in the remaining breast.

A study of the influence of pregnancy on the causation of mammary cancer by Miss Lane-Clayton from the records of twelve leading hospitals in Great Britain (1926) has disclosed a definitely greater frequency of breast cancer in women who were never pregnant. Peller, however (1940), found breast cancer equally frequent in women who were never pregnant and in those who had been pregnant, although when only women having borne children were considered the frequency of breast cancers was in inverse proportion to the number of children borne, that is, breast cancer occurred more often in women having 1 pregnancy than in women having borne several children. Kilgore (1929) found that a woman is three or four times more likely to have cancer in a remaining breast than is a woman with two normal breasts. Warren and Gates in an extensive study of multiple primary malignant tumors (1932) found only 47 instances in which there was evidence of the independent origin of cancer in both breasts.

Certainly the evidence shows that following mastectomy the second breast is subject to cancer in the same frequency as is the breast of a normal woman of the same age, and there is some evidence that cancer is more likely to develop in the second breast of a woman than in a breast of a woman who has never had breast cancer. FRANK B. QUEEN, M D

Radical Mastectomy VICTOR RIDDELL. *Brit J Surg*, 1948, 36, 113

This article does not introduce any new concepts in the surgical management of cancer of the breast, nor does it violate any of the principles of surgical pathology upon which radical mastectomy was founded and upon which it has stood the test of time. Emphasis is placed upon several of the factors which influence the prognosis, morbidity, and mortality.

The author obtains a biopsy of a suspicious breast tumor by entering directly into the mass through an incision in the skin immediately over it. The growth is not excised to examine it as this involves the opening up of large veins on the periphery by way of which metastases may be disseminated even if diathermy is used for the excision. The center of a hard growth is almost avascular so that the chances of dissemination are reduced to a minimum by this method.

Diathermy should be used with particular caution. The author believes that its use provides the most common cause for flap necrosis. No doubt it oc-

SURGERY OF THE THORAX

casasionally interferes with the blood supply of the flaps. If carelessly used for coagulation it can cause tissue necrosis, which in turn produces an exudation of serum and an increased liability to sepsis.

There should be no hesitation in sacrificing the nerve to the latissimus dorsi muscle if there is any question of its impeding the thoroughness of the block dissection of the axilla. There are occasions when there appear to be no enlarged lymph nodes and no visibly malignant tissue, and in these circumstances the nerve to the latissimus dorsi muscle should be isolated and preserved as deliberately as it should be removed in more advanced cases. If the nerve is sacrificed, little or no disability has been noted in these patients as compared with control cases and with the opposite side.

The area of skin available for fashioning the flaps must be planned in advance. A defect remaining at the end of the operation between the edges of the flaps has two disadvantages in that it can heal only by the aid of a skin graft or by granulations and scar tissue which form a patch vulnerable to subsequent postoperative therapy. The more serious disadvantage is that healing is often protracted so that the start of postoperative therapy is delayed to a point where its usefulness is open to question.

The technique of radical mastectomy is reviewed by the author in an attempt to place emphasis on the thoroughness of the procedure rather than on any special variation in the manner of its performance otherwise. The prevention of blood loss is of paramount importance. Of especial interest to American surgeons is the author's insistence that the medial flap should not be elevated until late in the operation. Elevation of the medial flap to the border of the sternum involves division of the branches and tributaries of the internal mammary vessels in three separate situations, first, when the initial incision is made into the subcutaneous tissues, second, as the base of the flap is approached, and, third, when the pectoral muscles are removed. By delaying the elevation of the medial flap until the perforating branches of the internal mammary artery have been secured, bleeding is reduced and the flap can be raised avascularly, time is saved because no vessels in the breast have to be ligated or coagulated, and few if any on the flap, and the vitality and warmth of the flap is preserved until the end of the operation. ORVILLE F. GRIMES, M.D.

TRACHEA, LUNGS, AND PLEURA

Thoracoplasty in the Treatment of Giant Tuberculous Cavities (La toracoplastia en el tratamiento de las cavernas tuberculosas gigantes) JUAN CARLOS BARBERIS
Rev. med. Rosario, 1948, 38, 657

The author regards the following technical conditions as necessary to obtain a good collapse in giant tuberculous cavities:

1. In each surgical stage no more than three ribs should be resected to avoid shock or acute displacement of the mediastinum.

2. Not more than 2 (exceptionally 3) should be allowed between each operative stage to avoid early ossification which would prevent collapse of the cavity.

3. Resection of the three first ribs, sometimes of the fourth rib, must be complete, the thorax must be disarticulated posteriorly and resected as far as necessary anteriorly, according to indications.

4. The posterior disarticulation must be performed without transversectomy to avoid elimination of points of insertion of the intertransverse ligaments and muscles which would result in definitive stiffness.

5. Together with resection of the upper ribs, intrapleural pneumolysis must be performed to the apex and a large part of the upper lobe, to facilitate concentric retraction of the lung, in which the latter has not lost its elasticity. Formation of transudate in the created space 48 hours after operation serves to push down the pulmonary stump in cases in which the lung has already lost its elasticity, for this reason, the author has never drained the extrapleural transudate but has relied on its action as a physiologic pleurodesis.

Generally, in a period of 45 days the author performs a subtotal thoracoplasty of eight ribs in four operative stages at intervals of 15 days: first stage, high, suprascapular; second stage, posterior, in the upper interscapulovertebra; third stage, anterior, in the parasternal zone; level of the second, third, and fourth ribs; and fourth stage, low posterior, in the lower interscapulovertebra.

The author reports 18 cases in which he operated within the past 8 years without having to resort to other means of collapse. The results in 8 patients (44.5 per cent) apparently cured, in 5 patients (27.8 per cent) with a quiescent condition, in 3 patients (16.6 per cent), outcome unknown, in 2 patients (11.1 per cent) discharged with collapse of the cavity, and in 0 patients (0 per cent) with negative results of examination for bacilli. Of 11 patients (61.1 per cent) deceased (1 from hemiparesis before the fourth stage was done, the other 10 from acute pneumopathy developing in 3 days after the thoracoplasty had been done), in 7 patients (38.9 per cent) operated upon less than a year previously.

RICHARD KEMEL

Studies in Lung Abscess Lung Abscess and Bronchial Carcinoma
R. C. BROCK
Guy's Rep., Lond., 1948, 97, 75

The association of a carcinoma with a lung abscess is sufficiently common to justify a separate consideration of the subject. In a series of 405 lung abscesses, bronchial carcinoma was the cause in 56 instances, or 13.8 per cent. In 30 per cent of 185 patients in this series who were over 45 years of age, the abscesses were associated with a carcinoma.

A lung abscess may be associated with, or precede, a carcinoma in three ways:

1. It may be due to a breakdown of the lung itself (35 cases in this series of 56).

Fig 1 (Brock) Diagrams to illustrate the ways of formation of a lung abscess associated with a primary bronchial carcinoma a, Primary abscess due to breaking down growth b, Secondary abscess occurring in obstructed infected lobe distal to a carcinoma Often more than one ab-

cess is present c, Secondary abscess in various sites caused by spill-over infection from a primary carcinoma in the left upper lobe d, Abscess in close association with a breaking-down growth also causing obstruction and infection of a lobe in which secondary abscesses develop

2 It may arise in an obstructed and infected part of the lung distal to the growth causing obstruction (17 cases)

3 It may be caused by bronchial embolism or spill-over from the primary growth and may be situated in a different lobe from the primary causal growth, or even in the opposite lung (4 cases)

When the abscess forms within the primary growth it may be called "primary", when it is not part of the primary growth it should be described as "secondary"

The primary malignant lung abscess usually represents a circumscribed mass. It is predominantly a squamous cell carcinoma. The size of the abscess cavity in proportion to the size of the whole mass varies considerably, but the thickness of the wall or, more specifically, the irregularity or nodularity of the cavity walls should assume an important role in suggesting the correct etiology. Erosion of the overlying ribs is highly diagnostic of malignancy.

In secondary abscess due to an obstructing bronchial growth, the pathologic picture is principally one of diffuse septic pneumonitis with gross septic bronchiectasis. The demonstrable abscess cavity may actually be a hugely dilated single bronchus.

In the spill-over types, the lung abscess represents an extension to another portion of lung (ipsilateral or even contralateral) of the septic process around a carcinoma, the latter often occurring in a segmental bronchus.

In the 56 cases reviewed, the left upper lobe was the predilected site for malignant abscess.

The onset may be insidious, accompanied by cough and a steady decline in general health, the condition is recognized as a lung abscess principally on its roentgenographic appearance, the septic features of the usual abscess being slight or intermittent. This is often the case in the primary type of malignant abscess.

In the secondary malignant abscess, even though the onset may be insidious, the septic features of the abscess predominate and include copious spu-

tum, often truly foul. Varying amounts of pus and blood may be present in the sputum.

The clinical picture may, of course, be intermediate between these limits. The accurate differentiation of a malignant from a nonmalignant abscess is not easy and is often impossible.

The treatment for malignant abscess is surgical extirpation. External drainage of the abscess is rarely indicated because only rarely can it be a useful palliative approach and it never offers a chance of cure. Occasionally, external drainage may provide the histologic proof of malignancy, and, when this occurs, resection should be undertaken unless a definite contraindication exists, when removal of the lung and the chest wall sinus should be done. A bold approach to the management of a lung abscess suspected of being associated with carcinoma is justified.

This excellent article is illustrated by diagrams, roentgenograms, and photographs of specimens, and is accompanied by 4 case histories illustrating the points under discussion.

HIRAM T. LANGSTON, M.D.

Ninety Abscesses of the Lung Treated by Bronchial Aspirations (90 Abscès du poumon traités par bronchoaspirations) J. M. LEMOINE and Y. ROSE *J fr med chir thorac*, 1948, 2, 432

Ninety patients with pulmonary abscesses were treated by bronchial aspiration. Of these, 45 (50%) were regarded as being cured, 21 (33%) benefited, and 24 (27%) not benefited. The procedure is contraindicated in seriously ill patients, those who are markedly debilitated, those with excessive expectoration, and those with prolonged fever.

The average duration of illness was 6 months. Among the 90 patients 75 were men and 15 women. Their ages were between 30 and 60 years. In 83 per cent of the men, the cause was undetermined, in 50 per cent of the women it was traced to surgical intervention, aspirated foreign bodies, or puerperal fever. Sputum production varied between 50 and 600 c.c. per 24 hours. Roentgenologically, 65 of the

patients showed a distinct cavity with surrounding opacity, 10 revealed an isolated cavity without notable density, and 15 revealed merely pulmonary density without cavitation. Eighty-four cases were unilateral, 56 being on the right side and 28 on the left. Forty-six were in the superior lobes (31 right, 15 left), 34 were in the inferior lobes (21 right, 13 left), and 4 in the middle lobes.

Lipiodol bronchograms were not taken because of the danger of exacerbation and the persistence of lipiodol as a hindrance to further roentgenological studies.

Bronchoscopic aspirations varied from 1 to 55 with an average of 10 treatments in the cured and ameliorated cases. In 13 of the 45 cured patients, the roentgenograms following bronchoscopy were normal, in 32 patients slight fibrosis was present.

No apparent correlation was found between the extent of the disease, its duration, the size of the cavity, the fever present, the type and amount of sputum, and the prognosis for recovery when this method of treatment was used.

Before the introduction of penicillin, most of the patients with pulmonary abscess were treated as those in the series presented here, especially when they were not suitable for surgery. Because of the encouraging results obtained in this group there may yet be a place for repeated bronchoscopic aspirations in the treatment of pulmonary abscess.

C. FREDERICK KITTLE, M.D.

Refinement of Technique in the Cytologic Diagnosis of Tumors of the Bronchus (*Précisions techniques sur le diagnostic cytologique des tumeurs bronchiques*) JACQUES DELARUE, JEAN PAILLAS, Y. BERGEROT-BLONDEL, and GIACOBBI. *J fr méd chir thorac*, 1948, 2, 501.

For a period of several months the authors have been systematically applying the cytologic method in the diagnosis of bronchial tumor. This method is attempted only in those cases in which bronchoscopy is negative and the nature of the growth can not be determined by any other method. In their reported material, consisting of 41 cases, are 26 cases diagnosed from a biopsy on specimens procured by bronchoscopy, and 17 cases diagnosed by the method of cytologic examination of the sputum, or of bronchial secretions. The secretions were procured by introducing a sound or canula under bronchoscopic control as far as possible into the involved bronchus, as determined roentgenologically, and procuring the material by scraping the bronchial walls. The sputum was utilized in 4 cases and the bronchial scrapings in 13 cases.

The usual technique on the sputum and secretions was to harden the mucous, mucopurulent, or even bloody material in 30 per cent formalin, imbed it in paraffin, and cut with a microtome. The thin sections were then stained with hematoxylin-eosin and mounted as microscopic slides.

The number of possible tumors which may have been missed by all techniques combined is, of course,

impossible to say because of the brief period of time elapsed, however, the percentages of positive results are not very different from those reported by other authors (Wandall, Herbut and Clerf, and Woolner and Macdonald) who have been working longer with the method and whose results have been verified by the subsequent development of metastasis or by autopsy.

The authors consider that in the light of the improved techniques and better results, the previous attitude of condemnation of cytologic diagnosis of cancer of the bronchus will have to be revised. Two grave disadvantages of the method are admitted. The first is that the method will not succeed in the cases of enclosed tumors of the pulmonary periphery, these tumors are mainly adenomatous cancers and are just the neoplasms which are most amenable to surgical excision. The second disadvantage resides in the fact that the cytologic examination does not always permit of differentiating the histologic type of the cancer, whereas experience has led to the belief that the different types require different modes of treatment. Particularly is this seen in the small cell type of cancer which is more properly included in the sphere of irradiation therapy.

All in all, however, the authors consider that the method of cytologic diagnosis of tumors of the bronchus is an excellent one which should be applied systematically in all cases in which the endoscopic methods have failed.

In the discussion, Métras states his belief that the method of cytologic diagnosis is no more than one of probability, for in the chronic lesions of tuberculosis perfectly superposable histologic appearances are encountered.

Bérard thinks that when hemoptysis and atelectasis are present it would be dangerous to delay the treatment for the purpose of procuring a certain diagnosis, since the case will prove to be one of cancer 9 times out of 10.

Monod asserts that in his experience the only 3 year survivals have been patients who were operated upon without waiting for a certain preoperative diagnosis.

Paillass concludes that, despite the assertions of Métras, the differentiation between cancer and non-cancer by this method should result in very few mistakes. It is true that the polymorphism of certain cancers may provide difficulties, however, this difficulty exists chiefly between the adenomatous cancers and the small cell cancers, never between the small cell cancer and the malpighian carcinoma.

JOHN W. BRENNAN, M.D.

Bronchogenic Carcinoma of the Middle Lobe and Segmentary Bronchitis (*Cancer bronchique du lobe moyen et bronchite segmentaire*) L. CURTILLET and PORTIER. *J fr méd chir thorac*, 1948, 2, 422.

The authors discuss the importance of suspecting bronchogenic carcinoma in cases of pneumonitis involving the middle lobe of the lung. The symptomatology illustrates the difficulty of deciding

whether or not such a process is a primary inflammation or whether it is secondary to an obstruction of the lobe bronchus by tumor

The authors present the case history of a 58-year-old man whom they followed up for 9 months. A diagnosis of middle lobe bronchiectasis had been made before exploratory thoracotomy was done and endobronchial carcinoma found. The inaccessibility of such tumors to bronchoscopy is discussed as well as the indecisive picture presented by ordinary chest roentgenograms and lipiodol studies. Because of the high incidence of pulmonary carcinoma the authors advise early thoracotomy in instances of pneumonitis which do not respond quite readily to medical therapy.

The surgery which they advise for bronchogenic cancer is that procedure which will completely remove the neoplasm, whether it be lobectomy, double lobectomy, or pneumonectomy.

C. FREDERICK KITTLE, M.D.

Covering of Lattice Lung and Residual Apical Pleural Cavity by Transplantation of a Tube Pedicle Flap (Gitterlungenverschluss und Spitzenresthöhlenausheilung durch Rundstiellappendeckung) HELMUT GOEPEL *Chirurg*, 1948, 19: 458

The author reports 2 cases of extensive lattice lung and residual apical pleural cavity resulting from gunshot wounds which were successfully closed and healed by transplantation of a delayed, caterpillar type, tubed pedicle skin flap. In both cases the defect was located in the right infraclavicular region. The flap was prepared in the left flank, half of the flap being fashioned as a flap covering and half as a tube pedicle. The pedicle end was then transplanted to the dorsum of the left hand as an intermediate step. Before the final transplantation to the lattice lung field, the flap was completely freed from its parent bed and sutured back in place. About 3 weeks later the scar surrounding the area and the surface of the lattice lung was freshened, epithelium and mucous membrane was removed from the surface, and the flap was sutured directly over the new, granulating bed.

Healing in both cases occurred with a minimum of inflammatory reaction. A residual bronchial fistula was closed with the base of the pedicle freed from the hand after about 3 weeks. Later the middle portion of the pedicle was used to provide skin covering for the surface of the residual cavity. In both cases the result was good.

The advantages of the method are (1) the skin flap is taken from a distant site, so that scar tissue about the site of the defect is avoided, (2) extensive operative procedures near the defect are eliminated, and (3) the disadvantages of muscle transplants are avoided. The author believes that it is better to dress the surface of the cavity with healthy skin than to try to fill the cavity with plastic material. In some cases a small recess into the cavity will remain, but the chronic infectious process will be eliminated.

JOHN L. LINDQUIST, M.D.

Indications for Pulmonary Resection with Special Reference to Extent of the Operation EMIL A. NACLERIO *Am J Surg*, 1949, 77: 140

Principles applying to the surgery of extrapulmonary tissues likewise govern the therapy of intrathoracic diseases. In malignancies the entire organ together with its regional lymph nodes and intervening lymphatics is removed. Prompt intervention is an obligatory prerequisite for the optimal treatment of cancer. In consideration of inflammatory processes, surgical extirpation and drainage with as little disturbance of the normal structures as possible should be done.

Removal of the entire lung or a portion is indicated when the tissue is so seriously diseased that its retention will either interfere with the well-being of the patient or cause his death. These indications may be conveniently classified as:

- 1 Primary new growths of the lung
 - a Malignant
 - (1) Carcinoma
 - (2) Sarcoma
 - b Nonmalignant
- 2 Metastatic "solitary new growths"
- 3 Chronic suppurative disease
 - a Bronchiectasis
 - b Lung abscess
 - c Gangrene of the lung
 - d Chronic pulmonary disease with varying degrees of atelectasis, pneumonitis, and abscess formation (which do not clearly fall into the classification of either bronchiectasis or lung abscess)
 - e Chronic nonspecific pneumonitis
- 4 Tuberculosis
- 5 Fungus infections
- 6 Pulmonary cysts
 - a Nonparasitic cysts and cystlike cavities
 - (1) Congenital pulmonary cyst
 - (2) Cystic bronchiectasis
 - (3) Epithelialized cavities following pulmonary suppuration
 - (4) Pneumatocele (localized alveolar or lobular ectasia)
 - (5) Emphysematous bullae
 - (6) Pulmonary blebs
 - b Parasitic cysts
 - (1) Echinococcal (hydatid) cyst
- 7 Arteriovenous fistula
- 8 Traumatic injuries

A brief discussion of each clinical entity is given, emphasis being placed on diagnosis, prognosis, and indications for surgery.

C. FREDERICK KITTLE, M.D.

HEART AND PERICARDIUM

The Blalock-Taussig Operation for Morbus Coeruleus MAURICE CAMPBELL *Guy's Hosp Rep*, Lond., 1948, 97: 1

The steps that led to the development of the Blalock-Taussig operation for cyanotic congenital heart

disease are described. The fundamental requisite for success is that the cyanosis and disability should be mainly due to an inadequate blood flow to the lungs.

The cases of the first 18 patients chosen at Guy's Hospital and operated on by Blalock or by Brock are described.

The main features for which these patients were selected were persistent cyanosis from infancy with polycythemia and clubbing of the fingers and severe disability on walking. On radioscropy the heart showed little or no general enlargement, although most of the patients had some enlargement of the right ventricle, there was no undue prominence in the pulmonary arc and no visible pulsation in the pulmonary branches. The heart was sabot-shaped in less than half of the patients.

Most of them had a systolic murmur in the pulmonary area, often with a slight thrill. The pulmonary second sound was never much increased and was often diminished. None had a diastolic murmur. Also, most of the patients showed a preponderance of the right ventricle in the electrocardiogram with a large pointed P II wave. All were of normal mental development, but most were underweight. Squatting was noted in four-fifths of them, and panting after exertion was nearly as characteristic.

The operation was usually an end-to-side subclavian-pulmonary anastomosis on the side opposite to the aortic arch, this was done on the right side in one-fourth of the cases. The immediate disturbance caused by the operation is less than might be expected, and intravenous fluid is often not required and then only in small amounts. Many of the patients have a pleural effusion that often needs aspiration, but generally only once, other complications are not common.

Three of the 18 patients died, 1 could not be subjected to an anastomosis, and 1 did not benefit much, the remaining 13 patients were greatly benefited almost at once and the improvement has been maintained or increased for the 3 to 6 months that have elapsed since operation.

The color of the patients became nearly normal except for slight cyanosis on a cold day or after vigorous exercise and the capacity of the patients was wonderfully improved so that they could walk some miles and get about normally all day. The polycythemia disappeared quickly, but the clubbing of the fingers more slowly. The arm of which the subclavian artery had been divided gave no trouble.

The heart enlarged a little, as might be expected from the increased work, but generally the enlargement was only slight, and in the few cases in which the increase was moderate it did not appear to be progressive.

In the larger number of cases seen subsequently, Fallot's tetralogy seemed to be the probable diagnosis in about three-quarters of the patients with a congenital heart condition in which cyanosis dated from birth or early in life. In 80 per cent of these patients squatting was a common feature. The age

incidence of these patients is discussed. The ages of the patients and their mortality without operation justify a considerable risk for the improvement that can be obtained from the Blalock-Taussig operation.

An auricular septal defect, combined with some other defect causing cyanosis from birth or soon after, seems to be the most common abnormality contraindicating operation, although Eisenmenger's complex may be more common than would be thought from the paucity of reported cases. The condition of the pulmonary arterial branches in radioscropy is the most essential feature on examination, although the findings can generally be predicted in a patient with a typical history, appearance, and physical signs. In a doubtful case cardiac catheterization and angiocardiology should be decisive.

The article is amply illustrated by photographs, roentgenograms, and numerous tables.

HIRAM T. LANGSTON, M.D.

Treatment for Coarctation of the Aorta ROBERT E. GROSS *J Am M Ass*, 1949, 139: 285

The seriousness of the prognosis of coarctation of the aorta is brought out by the fact that only 26 per cent of patients in a postmortem series had lived a long life with little or no incapacitation, 22 per cent died from bacterial endocarditis or aortitis, 23 per cent died of rupture of the aorta, usually with hypertension, and 28 per cent died because of the hypertensive state, most frequently from cardiac failure or intracranial hemorrhage. The average age at death was 35 years.

The diagnosis of coarctation is made from physical observations and roentgenologic data. The pulsations in the lower extremities are greatly diminished or absent, the blood pressure in the arms is usually elevated and is decidedly above that in the legs, in contrast to the usual state of affairs, evidence of collateral circulation about the thorax is often observed, murmurs are variable, the heart is apt to be enlarged but the aortic knob is usually small, and there may be notching or scalloping along the inferior surfaces of the ribs where tortuous and pulsating intercostal arteries have eroded the bone. Angiocardiology with diodrast is most useful for an exact confirmation of the diagnosis and for visualization of the anatomic abnormality.

Operation is performed through the fourth left interspace. Noncrushing clamps are applied above and below the constricted area and the narrowed portion is cut away. End-to-end anastomosis with an everting mattress suture of silk is then carried out.

Among 60 operations for coarctation there were 7 deaths, only 1 of which was directly connected with the aortic abnormality. In 6 cases, exploration only was possible because of the conditions found, i.e., regional inflammatory changes or a very long segment of narrowed aorta, in 2 cases a subclavian-aortic anastomosis was done, and in the remaining cases, end-to-end aortic suture was accomplished. Forty-one patients had complete relief of hyperten-

sion, 3 had fair relief, and only 1 patient obtained no relief

In 1 patient, excision of the coarctation left a long gap which could not be closed by direct apposition of the ends. A 5 cm aortic graft from another person which had been preserved for a period of 30 days was successfully sutured into place and the patient was discharged from the hospital in excellent condition.

The lower age limit for operating on coarctation is probably 6 or 8 years, the upper age limit is difficult to define precisely. Excellent results have been obtained in patients in the late twenties, but greater satisfaction will be obtained in younger subjects.

JESSE E. THOMPSON, M.D.

Experimental Reconstruction of Cardiac Valves by Venous and Pericardial Grafts JOHN Y. TEMPLETON, III, and JOHN H. GIBBON, JR. *Ann Surg*, 1949, 129, 161

A technique has been developed in dogs to allow resection of a portion of the tricuspid valve and its replacement with a graft of vein or pericardium. The venae cavae and azygos vein are clamped temporarily and the right auricle is opened. Under direct vision a leaflet of the tricuspid valve is resected, the auricle is closed, and circulation is re-established. A graft is then prepared, either from a section of pericardium or a segment of azygos vein turned inside out. The circulation is again interrupted and the auricle re-opened. The graft is then inserted and sutured in place with silk stitches. The auricle is closed and circulation re-established.

Grafts were placed into 19 dogs, 7 of which survived from 3 weeks to 7 months after operation. Death in the others was due to ventricular fibrillation or neurologic damage, as a rule. Specimens of the grafts obtained at autopsy after 3 weeks were viable and firmly united to the wall of the heart. Anatomically and functionally the pericardium appeared to be more suitable than a vein as a source for the graft. In 5 control animals a portion of the tricuspid valve was resected and no graft was used. Postoperatively these animals had loud murmurs in contrast to the animals in which grafts had been used, which had only faint murmurs. All the control animals developed marked precordial thrills, 4 of the 7 animals in which grafts had been used developed systolic thrills in 3 weeks or more following operation.

JESSE E. THOMPSON, M.D.

Four Cases of Polypoid Tumor ("Myxoma") Within the Left Auricle of the Heart T. B. BREWSTER. *Guy's Hosp Rep*, Lond, 1948, 97, 64

This article is a report of 4 cases of polypoid tumors of the heart arising within the auricle.

The nature of such tumors is in dispute, as shown by a review of the literature. Some 200 cases have been reported, and these tumors have been considered as organizing thrombotic masses, or new growths of fibrous or myxomatous nature. No further conclusive evidence in this regard is given.

The clinical picture is often confusing, but may present itself as simulating mitral stenosis with relentless progression of cardiac failure unaffected by treatment, or it may mimic the embolic picture of bacterial endocarditis.

The absence of evidence of rheumatic fever and the relentless march of cardiac failure could lead to a suspected diagnosis during life. It has been suggested that embolectomy in appropriate cases might give a clue to the presence of this tumor if microscopic examination of the embolus was carried out.

The 4 gross as well as microscopic specimens are represented by photographs and the case histories are briefly given.

ESOPHAGUS AND MEDIASTINUM

Displacement of the Esophagus into a New Diaphragmatic Orifice in the Repair of Paraesophageal and Esophageal Hiatus Hernia K. ALVIN MERENDINO, R. L. VARCO, and OWEN H. WANGENSTEEN. *Ann Surg*, 1949, 129, 185

There are three main types of esophageal hiatus hernia: short esophagus with "thoracic" stomach (rare), normal esophagus, remaining in its normal situation, with the stomach in the hernial sac (paraesophageal), normal esophagus, with the stomach herniating through the hiatus and pushing the esophagus ahead of it into the sac.

Hiatus hernia is not an uncommon finding and is more frequent in females than in males. Symptoms vary and are related to the gastrointestinal tract, cardiovascular system, respiratory tract, or any combination of these. Most patients are past 40 years of age and are obese. X-ray examination is the most important single diagnostic aid. There is often no correlation between the size of the hernia and the severity of symptoms, and the hiatus hernia may be only incidental to a more serious lesion.

Medical management should be attempted in practically all cases. Surgical repair is justified after medical measures fail to give relief. The authors report a variation of the conventional method of repair. A transthoracic approach is preferred, although the transabdominal or combined thoracoabdominal approach may be employed. This repair entails displacement of the esophagus anteriorly and to the left, closure of the hiatus posteriorly by suture of the right and left crura of the diaphragm, and suture of the stomach immediately distal to the esophago-gastric junction to the edge of the diaphragm. When the tissues of the right and left crura are not satisfactory for suture, a new hiatus is created by an incision anterolaterally in the diaphragm; the esophagus is placed in the new position, and posterior closure is effected.

Thirteen cases without recurrence are reported. The transthoracic approach was used in 9 cases, the transabdominal approach in 3, and the transabdominothoracic approach in 1 case. Certain advantages and disadvantages of the various approaches are reviewed.

JESSE E. THOMPSON, M.D.

Surgical Treatment of Esophageal Perforations (Traitement chirurgical des perforations de l'oesophage) HORACIO RESANO *Rev chir*, Par, 1949, 68 1

Ninety per cent of perforating injuries of the esophagus are situated in the cervical portion. Most of them are caused either by foreign bodies or by instrumentation, especially esophagoscopy or attempts at extracting a foreign body.

The clinical symptoms include pain, dysphagia, fever, and subcutaneous edema. However, they are not present in all cases so that the diagnosis is missed frequently. More helpful are the radiological signs: increase of the tracheovertebral distance and a characteristic air bubble in this space (Fig 1).

Some writers recommend medical and antibiotic management and take recourse to surgery only in case of failure of such management. In contradistinction to these men, the author believes that early surgery should be done in every case, even if the diagnosis is not certain. A simple submucous abscess may be visualized with the esophagoscope and opened. In all other cases mediastinotomy should be done.

The esophagus can be approached from in front or from behind the sternomastoid muscle. The author prefers the posterior route because the evacuation and drainage of pus is more effective. The proximity of the thoracic duct does not present a danger. Necrosis of the carotid wall due to pressure of the cigaret drain was never observed by the author.

A transverse incision is made 2 cm above the left clavicle. The external jugular vein is ligated, the tendon of the omohyoideus and the middle cervical fascia are cut, and the esophagus is exposed posteriorly to the sternomastoid muscle and the large cervical vessels. If no perforation or only a very small one is present, a cigaret drain is introduced in the retroesophageal space and removed after 48 hours. If a small abscess is found, the drain is left in place and fixed to the skin with a suture. Large abscesses require bilateral drainage. The surgeon introduces a finger through the incision and passes it behind the esophagus and the great cervical vessels of the opposite side. A counterincision is made at the posterior margin of the right sternomastoid muscle and a curved forceps is introduced through it. Under guidance of the finger the forceps is passed from right to left until it reaches the wound of the operation. Here it grasps a cigaret drain which is passed in the opposite direction from left to right.

Incidents and Accidents in Bronchoscopy (Incidents et accidents de la bronchoscopie) R. KOURILSKY and M. MARIETTE *J fr méd chir thorac*, 1948, 2 534

The authors report 450 bronchoscopic examinations made on 300 patients. Excluded from the examination were cases of old fibrosis of the lungs

Fig 1 (Resano) Simple lateral roentgenography of a perforation of the cervical esophagus. 1, Air bubble (sign of Münchingerode), 2, increase of the retrotracheal space, and 3, deformation of the posterior aspect of the trachea. Note that under normal conditions this space never surpasses the width of the tracheal shadow.

with pulmonary insufficiency, aneurysms of the aortic arch, and cases of decompensation of the heart. Of the bronchoscopic examinations 210 were done on tuberculous subjects and the remainder were done on patients with cancer and other nontuberculous affections. No consideration was given to the simple elevations of temperature which lasted only for the first night.

Among the nontuberculous patients there were only 2 cases (0.8 per cent) in which the examination was followed by lengthy periods of fever, from 8 to 10 days, and transient roentgenologic modifications which did not last as long as the febrile reaction. The most frequent indication for bronchoscopy in these nontuberculous patients was that of pulmonary suppuration (150), bronchiectasis, chronic abscess, or suppurated cysts. The fact that the results were so uniformly innocuous may perhaps be partially explained on the basis of the preoperative and postoperative administration of penicillin, and on the coincidental bronchial instillations.

In the tuberculous patients the results were not so good. Especially in the cases of progressive ulcerative, or nodular, pulmonary tuberculosis. In fact, in 20 per cent of the patients the bronchoscopic examination was followed by an immediate progression of the condition. In about half of this group (11 cases) the reaction was limited to a febrile attack.

sion, 3 had fair relief, and only 1 patient obtained no relief

In 1 patient, excision of the coarctation left a long gap which could not be closed by direct apposition of the ends. A 5 cm aortic graft from another person which had been preserved for a period of 30 days was successfully sutured into place and the patient was discharged from the hospital in excellent condition.

The lower age limit for operating on coarctation is probably 6 or 8 years, the upper age limit is difficult to define precisely. Excellent results have been obtained in patients in the late twenties, but greater satisfaction will be obtained in younger subjects.

MISCELLANEOUS

Incidents and Accidents in Bronchoscopy (Incidents et accidents de la bronchoscopie) R. KOURILSKY and M. MARIETTE *J fr mtd chir thorac*, 1948, 2 534

The authors report 450 bronchoscopic examinations made on 300 patients. Excluded from the examination were cases of old fibrosis of the lungs

Fig 1 (Resano) Simple lateral roentgenography of a perforation of the cervical esophagus. 1, Air bubble (sign of Minnigerode), 2, increase of the retrotracheal space, and 3, deformation of the posterior aspect of the trachea. Note that under normal conditions this space never surpasses the width of the tracheal shadow.

with pulmonary insufficiency, aneurysms of the aortic arch, and cases of decompensation of the heart. Of the bronchoscopic examinations 210 were done on tuberculous subjects and the remainder were done on patients with cancer and other nontuberculous affections. No consideration was given to the simple elevations of temperature which lasted only for the first night.

Among the nontuberculous patients there were only 2 cases (0.8 per cent) in which the examination was followed by lengthy periods of fever, from 8 to 10 days, and transient roentgenologic modifications which did not last as long as the febrile reaction. The most frequent indication for bronchoscopy in these nontuberculous patients was that of pulmonary suppuration (150), bronchiectasis, chronic abscess, or suppurated cysts. The fact that the results were so uniformly innocuous may perhaps be partially explained on the basis of the preoperative and postoperative administration of penicillin, and on the coincidental bronchial instillations.

In the tuberculous patients the results were not so good. Especially in the cases of progressive ulcerative, or nodular, pulmonary tuberculosis. In fact, in 20 per cent of the patients the bronchoscopic examination was followed by an immediate progression of the condition. In about half of this group (11 cases) the reaction was limited to a febrile attack.

lasting from 5 to 10 days and then a return to normal, without at any time evidence of alterations in the lungs detectable by roentgenologic methods. In the other cases (9), the febrile attacks were accompanied by evident roentgenologic changes of progressive and enduring character. In 2 instances the examination was followed in a few days by death.

The authors are of the opinion that in these cases of progressive pulmonary tuberculosis with fever, an accelerated sedimentation rate, and roentgenologic evidence of an ulcerative or nodular type of tubercular pulmonary involvement, bronchoscopy should be practiced only for positive and definite indications, and that the patient should be protected by a course of streptomycin. JOHN W. BRENNAN, M.D.

Anesthesia for Operations for the Relief of Congenital Pulmonary Stenosis E. H. RINA, P. J. HELLIWELL, and A. M. HUTTON *Guy's Hosp Rep*, Lond., 1948, 97: 48.

This report deals in some detail with the anesthetic problems encountered during the performance of the Blalock-Taussig operation. It includes the period of time during which Blalock worked as Associate Surgeon at Guy's Hospital (London) in September, 1947.

The experience obtained from 42 patients is given, minutely and often dramatically. Three of these patients died on the table and 3 others died within 12 hours after the operation. The deaths are given as case reports. Nine of the 42 patients were operated upon by Blalock and the remainder by R. C. Brock.

The anesthetic technique employed is essentially that used and described by Blalock. The premedication given the English patients was heavier, consisting of full basal narcosis by means of nembutal with atropine gr. 1/100 for children. In adults omopon and scopolamine were followed by the intravenous administration of pentothal. Cyclopropane and oxygen with ether added, if indicated, are given in a closed system with carbon dioxide absorption,

through an endotracheal tube placed in a Butin anesthetized larynx. The principal deviation from the technique used by Blalock was the introduction of curare to obtain control of the respiratory efforts, particularly in young patients.

Some specific details of the anesthetic apparatus are given and illustrated by photographs.

The experiences with 3 cases of pulmonary valvulotomy are also given.

HIRAM T. LANGSTON, M.D.

Exploratory Thoracotomy in the Management of Pleural Empyema PAUL W. SANGER *J Thorac Surg*, 1948, 17: 756.

The incidence of empyema secondary to lobar and lobular pneumonia is now less frequent than empyema secondary to ruptured bronchiectatic abscess, infected hemothorax, ruptured subdiaphragmatic abscess, traumatic empyema, ruptured pulmonary abscess, cancerous or noncancerous, and as a consequence of inadequate surgery for postpneumonic empyema.

After intelligent conservative measures have failed, exploratory thoracotomy is the treatment of choice in present-day pleural empyema. If these cavities are not explored, the likely consequences of a long morbidity, superimposed on the inconvenience of a drainage tube or sinus tract, must be accepted. The compressed lung may never completely reexpand unless decortication is done. This radical attack is justified only after the preoperative studies for the underlying disease have been exhaustive, the hematocrit reading is 50 or above, ample blood is available for the operation, penicillin or streptomycin can be given preoperatively and postoperatively, and a competent anesthetist trained in endotracheal anesthesia is assured.

Representative case reports are given in an attempt to establish the indications for thoracic exploration, which in reality is conservative, by reducing the morbidity and preventing economic and psychological bankruptcy.

SAMUEL KAHN, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Strangulated Femoral Hernia Relationship of the Contents of the Hernial Sac to the Clinical Manifestations and Prognosis J. PARRAN JARBOE and JOSEPH H. PRATT *Am J Surg*, 1949, 77 172

By careful review of the clinical manifestations exhibited in 104 cases of strangulated femoral hernia it is obvious that acute strangulating types of small intestinal obstruction produce a very dramatic onset. The rapid progression of symptoms and signs indicates the rate of pathologic degeneration within the hernial sac. Therefore, when a segment or loop of the small intestine is strangulated in the femoral ring, the clinical picture presented is one of acute intestinal obstruction with such various degrees of prostration and shock that the femoral hernial process is often unheeded.

When abdominal or pelvic structures other than portions of small intestine are strangulated, the primary symptoms and signs usually indicate acute femoral herniation, whereas late manifestations may be referable to the structures involved. However, in all cases of strangulated femoral hernia the character and severity of the initial clinical symptoms and signs indicate the grave seriousness of the disease. Immediate cognizance of these manifestations should assure earlier surgical treatment and a more favorable prognosis.

It is acknowledged that numerous factors contribute to the high fatality rate associated with strangulated femoral hernia. Many of these contributory elements are individual responsibilities that offer few prospects for improvement of this situation unless the layman is re-educated to recognize the manifestations of impending strangulation. Too often the liability for fatalities is attributed to the advanced age of the patients without sufficient consideration and recognition of other probable causes for failure.

It has been demonstrated in the 104 cases of strangulated femoral hernia studied that age alone is not ample justification for the rendering of an unfavorable prognosis. It is the authors' observation and conclusion that the prognosis should be determined after evaluation of the pathologic condition of the strangulated viscera when they are visualized and treated at operation. In cases of strangulation of parts of the small intestine, when surgery has been delayed and irreversible pathologic changes have taken place, the prognosis is very grave for a person of any age. Since physical resistance in the aged is materially lowered, such persons are benefited most by early surgical treatment, but the prognosis should be influenced more by the condition of the strangulated viscera than by the factor of age alone.

The grave seriousness of strangulated femoral hernia involving a segment or loop of small intestine has been discussed. If the clinical evidence is considered and interpreted as being directly indicative of the degree of strangulating obstruction, perhaps many operations may be performed earlier before irreversible pathologic changes occur.

An intimate relationship has been found to exist between the character of the contents of the hernial sac and the clinical manifestations. Careful evaluation of these components is essential for the rendering of a dependable prognosis. It is hoped that adequate realization and a more comprehensive understanding of the serious problems presented by strangulated femoral hernia will result in benefits for everyone concerned.

Treatment of Acute Peritonitis W. A. ALTEMEIER
J Am M Ass, 1949, 139 347

There are two types of septic peritonitis: a primary type which usually occurs in children and is caused by the pneumococcus or a hemolytic streptococcus, and a secondary type having a polymicrobial causation and arising from perforation or leakage of an intra-abdominal viscus. The commonest factor in the secondary type is an infected appendix.

There is still no specific treatment for acute septic peritonitis, and successful management is dependent on good surgical intervention aided by early and correct diagnosis, chemotherapy, and adequate preoperative and postoperative care.

The author reviews 598 cases of acute septic peritonitis secondary to acute appendicitis, perforated peptic ulcers, and penetrating wounds of the abdomen in which the patients received chemotherapy in addition to other measures. A comparison of the results obtained in 685 similar cases treated without chemotherapy with those in cases in which chemotherapy was used reveals that the mortality has been reduced approximately 60 per cent recently and that this reduction is apparently due to the effects of chemotherapy.

Since most cases of acute septic peritonitis are secondary to lesions of the alimentary tract, it is the practice at Cincinnati General Hospital to operate as soon as the diagnosis is made. In the neglected, or moribund patients, surgery has been postponed and conservative therapy used until localization or improvement might occur. Among 258 patients with complicated acute appendicitis, 167 had peritonitis and 53 had appendiceal abscess. All but 10 patients were operated upon with a postoperative mortality of 4.8 per cent. Likewise, in a series of 179 patients with perforated peptic ulcers and peritonitis, treated in the same period, 169 underwent operation with closure of the perforation, and 10 did not, because of their moribund state in 8 instances, and the prolonged period of elapsed time since per-

foration in 2 cases The postoperative mortality was 7.6 per cent

Patients with appendical abscesses generally have been treated conservatively unless signs of infection did not diminish within from 24 to 48 hours, in which case plans for operation were made The mortality among the 13 patients who were treated by incision and drainage without appendectomy was 15.3 per cent, and among 35 patients who underwent appendectomy with drainage, 5.7 per cent Intra-abdominal abscesses other than appendical abscesses have been incised and drained as soon as their presence has been determined and localization has occurred

In cases of perforated peptic ulcer and penetrating wounds of the abdomen, the peritoneal cavity is not drained If the retroperitoneal tissues are contaminated, drainage is established through a stab wound in the flank Drainage was used in 204 of 248 patients operated upon for appendical peritonitis or abscess Careful removal of excessive exudate by suction has been done as part of the operation

The author recommends the following chemotherapy for effective treatment of acute secondary peritonitis the parenteral administration of penicillin and sulfadiazine, the combined use of penicillin, streptomycin, and sulfadiazine, or the injection of large doses of penicillin When several drugs are used, the dose of each should be therapeutically effective The dose of penicillin is 100,000 units given at 2 or 3 hour intervals In severe infections the dose may be 500,000 units or more every 2 or 3 hours Intraperitoneal chemotherapy is not used

When penicillin and sulfadiazine were used postoperatively in patients with perforated peptic ulcer the postoperative febrile period was 6.3 days, whereas it was 8.0 days when penicillin alone was used, and 12.4 days when only sulfadiazine was given The over-all mortality in patients with perforated peptic ulcer improved to 9.3 per cent when chemotherapy was used, as compared to 26.6 per cent in earlier patients treated without chemotherapy In peritonitis or abscess secondary to appendicitis, the mortality was reduced to 4.9 per cent when chemotherapy was used as compared to 14.5 per cent in earlier cases

Secondary peritonitis is a synergistic infection produced by the accumulative action of various bacteria which singly have a low virulence From 3 to 7 different species of bacteria can usually be cultured from any given case Penicillin in large doses is probably the most effective single agent available in the treatment of peritonitis even though most of the bacteria concerned are gram-negative Penicillin does not effect *Escherichia coli* and this organism is not truly pathogenic in the majority of instances

In patients treated with penicillin there is a lower incidence of cellulitis and necrotizing infection in the abdominal wound than in patients receiving no chemotherapy

Sulfadiazine or sulfamerazine are valuable adjuncts in the treatment of peritonitis and their

effect is considerably enhanced when used in combination with penicillin

Streptomycin is not as effective as penicillin Its greatest value is in the treatment of early spreading peritonitis and it is of questionable value in localized peritoneal suppuration or severe established peritonitis The authors use it in combination with penicillin and sulfadiazine and in cases that have failed to respond to penicillin alone or to penicillin and sulfadiazine
FREDERICK W PRESTON, M.D

GASTROINTESTINAL TRACT

Pseudoulcerative Gastritis (La gastrite pseudoulcero) Augusto Picco *Arch ital chir*, 1948
70 382

The author describes 6 cases of chronic gastritis with symptoms of gastroduodenal ulcer, but no evidence of ulcer in the resected portion of the stomach

The differential diagnosis between pseudoulcerative gastritis and round ulcer is difficult even with gastric analysis and x-ray examination

In 5 cases microscopy showed a follicular hypertrophic gastritis, while in the sixth case follicular atrophic gastritis was observed

The author describes two different types of inflammation One involves the mucosa, and corresponds to the classical type of inflammation, with parvicular (small cell) infiltration and the formation of lymphatic nodes and follicles The other type involves the mesenchymal tissue and is the type of serous inflammation with profound edema and primary fibrosclerosis of the connective tissue This is caused by primary alterations of the capillary walls due to penetration of toxic substances through the mucosa rendered permeable by the inflammation

In these cases medical treatment, which should always be tried, usually produces only a slight improvement over prolonged periods

Usually surgery must be resorted to and then cure will be obtained only after ample gastric resection
LUCIAN J FRONDOTI, M.D

Hypertrophy of the Pylorus in an Adult with Massive Eosinophil Infiltration and Giant-Cell Reaction H J BARRIE and J C ANDERSON *Lancet*, Lond, 1948, 2 1007

The authors reported the rare and interesting single case of a 27 year old woman with a 2 weeks' history of constant circumumbilical pain intense enough to keep her awake at night, and of pain and a feeling of distention between the breasts immediately after taking food Vomiting after every meal had relieved this pain Four years previously the patient had had a similar but less severe episode associated with melena which lasted a fortnight Eggs, pastry, and bacon had caused indigestion between these two attacks There was no personal or familial history of asthma or urticaria Physical examination revealed a furred tongue, tachycardia of 130 beats per minute, and slight tenderness to palpation in the epigastrium and the right iliac fossa

The barium meal showed a smooth filling defect involving the greater curvature of the prepylorus with a small residue in the stomach after 6 hours. The blood count showed a hemoglobin of 120 per cent, 6,300,000 red blood cells per cubic millimeter, a color index of 1, 17,000 white blood cells per cubic millimeter with 18 per cent of eosinophils. Two weeks later the white blood cell count numbered 11,800 per cubic millimeter with 31 per cent of eosinophils.

A partial gastrectomy with an anterior gastroenterostomy and an entero-anastomosis was performed. The surgical specimen showed concentric hypertrophy of the muscular coat of the stomach, pylorus, and duodenum, with massive eosinophile infiltration of the pylorus and peculiar para-arterial giant-cell follicles.

The authors believe that this is an example of true organic intestinal allergic reaction. This patient did not tolerate certain foods well, she had constant blood eosinophilia and a localized tissue eosinophilia of the pylorus, and there were giant-cell follicles in the pylorus which closely resembled follicles found in the heart muscle of patients who have become sensitive to neoarsphenamine.

Barrie and Anderson demonstrated the possibility that organic changes in the stomach may be caused by allergic reactions. The authors have been unable to find a similar published report.

ROBERT TURELL, M D

Diagnosis of Gastric Neoplasms H MARVIN POLLARD, HENRY C BRYANT, MALCOLM BLOCK, and WINSTON C HALL. *J Am M Ass*, 1949, 139 71

Improvement in the end result of gastric care can be expected only from earlier diagnosis of the lesions. In the cytologic examination of gastric secretions, a higher percentage of negative results occur because of (1) rapid deterioration of cells in the gastric fluid unless immediate fixation is done, (2) the absence of exfoliation in scirrhous carcinomas, and (3) the frequent presence of swallowed foreign cells from the nasal, pharyngeal, tracheal, and esophageal mucosæ. Since 1947 the authors had studied 326 gastric aspirations done on 278 patients. This group was studied because they all had gastrointestinal complaints. The technique was to aspirate a fasting specimen, and to add to the specimen an equal volume of 95 per cent alcohol. The sediment, after centrifugation, was smeared and fixed, and the usual solutions were used for staining and preparation. All slides were studied by the same pathologist, who estimated that positive slides can be evaluated quickly, while approximately 20 minutes were necessary before discarding a negative preparation. The most dependable sign of malignancy, invasion of the surrounding tissues, is not available in this type of examination.

The material studied was divided into four general categories.

In the first group of patients, in whom there was no clinical evidence of neoplasm, 86 per cent of the

aspirations were thought to contain no malignant cells, 10 per cent were indefinite, and 4 per cent were falsely reported as positive for carcinoma.

In the second group, 43 patients showed no histologic evidence of neoplasm. In this group, only normal cells were found in 72 per cent, in 9 per cent the cells were indefinite, while in 10 per cent it was believed that malignant cells were identified.

In the third group, 20 patients had a final clinical diagnosis of gastric carcinoma, but there was no histologic confirmation. No malignant cells were found in the gastric contents in 60 per cent (12), while a positive report was made in 40 per cent (8).

In the fourth group, in which 41 persons were proved histologically to have gastric carcinoma, no recognized malignant cells were seen in 22 cases (53 per cent), and 5 cases (12 per cent) were indefinite. Malignant cells were found in 14 cases (35 per cent).

In the total study, 59 per cent of the aspirations reported as positive were confirmed by clinical and histologic study. On the other hand, when the aspiration report was negative, results in 85 per cent of aspirations coincided with the clinical and histologic study. In all the cases with a final diagnosis of carcinoma, the result of the aspiration technique was correct in 36 per cent. On some occasions, the cytologic study was an indication for exhaustive clinical study. Final conclusions cannot be drawn. There are several factors of importance: (1) the experience of the pathologist with this method, (2) the difficulty of obtaining good smears because of obstruction, and (3) the number of aspirations done in an individual case.

At the present time this method should not be used as an exclusive basis for either a positive diagnosis or a positive exclusion of gastric neoplasm.

ROBERT E FLORES, M D

Benign Tumors of the Stomach. A Case of Lipoma Submucosa Ventriculi Simulating Cancer of the Stomach HENNING PAABY. *Acta chir scand*, 1949, 97 381

The author reports a case of large, submucous lipoma of the stomach, simulating cancer of the stomach. It was removed by resection.

The frequency of benign tumors of the stomach is stated very differently by the various authors. In 13 per cent of a material of operations comprising 2,195 cases of tumor of the stomach, the tumor was found to be benign. The occurrence of these tumors is more frequent than generally supposed.

The classification of these tumors varies. The tumors are divided, according to their histological structure, by Minnes and Geschickter into the following three main groups: (1) epithelial—comprising adenomas, adenopapillomas, fibroadenomas, and others, (2) mesenchymal—comprising leiomyomas, fibromas, lipomas, angiomas, and others, and (3) the pseudoneoplastic—comprising, among others, dermoid cysts, and blood cysts.

The etiology of the benign tumors is unknown. Achylia is of very frequent occurrence in the epithel-

lial tumors Haring, in a work on the connection between pernicious anemia and polypous tumors of the stomach, demonstrated that from 10 to 14 per cent of the patients with polypi of the stomach suffer from pernicious anemia, and stressed the importance of undertaking an examination of the blood in these patients as well as an x-ray examination of the stomach in all patients with pernicious anemia The significance of the benign tumors of the stomach is undoubtedly first and foremost their tendency toward malignant degeneration The tendency of the benign tumors to give clinical symptoms will, as a rule, depend on their size, as the great majority of the small tumors give no, or only vague, symptoms The symptom of most frequent occurrence is anemia, caused by hemorrhage Another symptom of fairly frequent occurrence—and rather a characteristic one—is acute stenosis Such attacks occur most frequently in association with small stalklike tumors localized near the pylorus

An important diagnostic aid is the x-ray examination, as the tumors often display characteristic signs It is difficult to diagnose the small polypous tumors roentgenologically, but in most cases they are best seen in examination of the mucous membrane with a small quantity of contrast medium and with compression They will then appear in the form of scattered, roundish rarefactions In some cases the tumor forms a well defined defective filling, surrounded by a natural relief of mucous membrane As a rule, peristalsis is normal, however, it is not normal if the tumor is ulcerated Recesses are of fairly rare occurrence and are never associated with spasms When a recess occurs—corresponding to an ulceration of the tumor—the usual convergence of folds of the mucous membrane will, as a rule, be absent, and the recess will often be large, of a punched appearance, with smooth walls, and without mounded edges

The treatment of benign tumors of the stomach will always be operative, partly because of the risk of malignant degeneration and partly because of the difficult diagnosis in connection with the frequently severe symptoms

CHARLES BARON, M D

Neurofibroma EBEN ALEXANDER, JR., and ROBERT M JAMES *Ann Surg*, 1949, 129 267

Hourglass neurofibroma, often referred to as perineural fibroblastoma, is sometimes found in the thoracic spinal canal and thoracic cage The tumor is benign Roentgenologically, it may erode the adjacent ribs and vertebrae

This tumor is often mistakenly diagnosed as lung carcinoma Radiation therapy produces no good results This serves to emphasize the fact that a tumor should not be irradiated without pathological proof as to its malignancy

The authors report a case of neurofibroma that was at first diagnosed as bronchogenic carcinoma It was given a trial course of irradiation with no response, and subsequently operation was done with complete relief of the symptomatology and physical findings

MAURICE D SACHS, M D

Mechanism of the Postgastrectomy Syndrome

DAVID ADLERSBERG and ERNST HAMMERSCHLAG
J Am M Ass, 1949, 139 429

The authors state that at present partial gastrectomy is the method of choice in the surgical treatment of peptic ulcer While the results are generally good, a certain number of patients (from 6 to 38%) present a group of symptoms termed the postgastrectomy syndrome

The symptoms may be divided into "early" and "late" postprandial symptoms The early symptoms are epigastric pressure, nausea, fullness, eructation and belching, dizziness, and occasional vomiting These early symptoms are attributed to mechanical factors of the small stomach with its rapid filling, rapid emptying, and distention of the jejunum with subsequent mesenteric irritation The late symptoms are headache, fatigue, weakness, perspiration, palpitation, dizziness, shortness of breath, and occasionally precordial pressure It is demonstrated that these symptoms are due to hypoglycemia secondary to an exaggerated postprandial hyperglycemia This may result from an increased insulin sensitivity A combination of these mechanical and chemical factors, together with distinct psychoneurotic disturbances with a tendency toward fixation and overemphasis of symptoms, causes this syndrome

Opinion concerning prophylaxis is divided, however, agreement prevails in regard to treatment Early symptoms are treated by frequent and small feedings The late postprandial symptoms are favorably affected by a high protein, high fat diet, with moderate amounts of carbohydrate The slow and gradual release of carbohydrate from protein results in a moderate elevation of the blood sugar level and so prevents the secondary hypoglycemia

ELY ELLIOTT LAZARUS, M D

Immediate and Late Results in the Treatment of Perforated Gastroduodenal Ulcer (Esiti prossimi e remoti della cura dell'ulcera gastro-duodenale perforata) GIUSEPPE SPADARO *Gior ital chir*, 1948, 4 603

The author reviews 100 consecutive cases of perforated gastroduodenal ulcer at Pelligrini Hospital in Naples Of these, 64 were gastric and 36 duodenal The over-all mortality was 18 per cent However, in the period from 1934 to 1940, there were 15 deaths in 49 cases, a mortality of 30.6 per cent, while in the period from 1941 to 1947 there were 3 deaths in 51 cases, a mortality of 5.8 per cent, these figures show a marked improvement This is attributed to better technique, antibiotics, and earlier diagnosis and treatment The postoperative mortality was minimal following simple closure of the perforation and after resection It was highest when gastroenterostomy was performed The best results followed simple closure when other factors were equal Eight patients were subjected to resection with 1 death (12.5 per cent)

As to the late results, the author differentiates between acute and chronic ulcers In acute ulcers

simple closure is followed by a definite cure in the majority of cases. In chronic ulcers simple closure results in cure in 50 per cent of the cases. Gastric resection gives a very high percentage of cures, while gastroenterostomy gives the poorest results.

As a result of this review the author recommends the following:

1. Acute ulcers should be treated by simple closure, regardless of the interval before operation.

2. Chronic ulcers when seen within 6 hours of perforation, and when the general condition permits, should be treated by gastric resection. If they are seen after 6 hours, or if the condition of the patient is precarious or there is evidence of peritonitis, simple closure should be done.

3. In cases in which operative intervention is not advisable one may resort to constant or intermittent suction as recommended by Bedford and Turner.

The author concludes by stating that the surgeon should never open an abdomen with a pre-established program but that the opened abdomen should dictate to the surgeon the procedure to be followed.

LUCIAN J. FRONDUCCI, M.D.

Experimental Research on the Behavior of the Duodenal Stump Following Exclusion Resection (Ricerche sperimentali sul comportamento del moncone duodenale nella resezione escludente) L. VERNETTI *Arch ital chir*, 1949, 71, 3

The author discusses the advantages of removing the mucosa from the antral portion of the stomach when performing the exclusion operation of Finsterer. He then describes experiments performed on dogs and dissections performed on cadavers. These were performed to determine the relative value of the methods used to remove the mucosa.

In the first group of dogs, he dissected the mucosa down to, or beyond, the pylorus, then ligated it as far down as possible and excised the proximal portion. In another group he dissected the mucosa as far as possible and then excised it without ligating it. In a third group he made a circular incision proximal to the pylorus, a longitudinal incision over the anterior portion down to the duodenum, and then coagulated the mucosa under direct visualization with the electric cautery. The dogs were sacrificed at different intervals. On gross examination there was not much difference. However, microscopic studies revealed that the best healing took place when the mucosa was excised and not ligated. In dogs in which the mucosa was ligated, a collection of sanguineous fluid was found between the ligature and the sutured seromuscular walls which, it was believed, might endanger the suture line and cause a leak. The use of the cautery caused inflammatory and hemorrhagic reactions which also endangered the ability of the suture line to hold.

The dissections on some cadavers were performed so as to isolate the mucosa distally without entering the lumen. In other cadavers a circular incision was made through all layers, then a longitudinal incision, perpendicular to the first incision and over the an-

terior surface of the antropylic region, was made to expose the mucosa and thereby allow its dissection under direct visualization. In others the mucosa was removed with a cutting spoon according to the method of Burkle. The author believes there is no difficulty in dissecting the mucosa down to the pylorus, regardless of how it is done. However, if the mucosa is to be dissected beyond the pylorus and in the first portion of the duodenum it becomes difficult. With use of the longitudinal incision, dissection is much easier as then the mucosa can be separated under direct vision. The use of the cutting spoon or curette was not satisfactory as all of the mucosa was not removed.

LUCIAN J. FRONDUCCI, M.D.

Surgical Treatment of Polyps of the Large Intestine

RICHARD B. CATTELL, *Am J Surg*, 1948, 76, 733

Cattell stated that in spite of the fact that now colonic malignant lesions come to resection about 2 months earlier than they did 10 years ago, and in spite of improvements in surgical procedures, the results observed 5 years or more after resection have not been improved appreciably. The 5-year survivals have remained in the vicinity of 50 per cent. He believes that the greatest opportunity in the future for the improvement of results lies in the discovery and the elimination of benign polyps which he regards as premalignant lesions.

The incidence of colonic polyps has varied from 2 to 20 per cent in reported series. The incidence of polyps in patients with proctologic symptoms who are given a proper proctologic survey varies from 5 to 10 per cent. It is assumed that at least 3 per cent of adult patients have benign polyps. Since only one-third of these patients with benign polyps have

Fig 1 (Cattell). The sigmoid has been freed and the polyp located. The diagram shows polyp being displaced proximally with a dimple appearing at its attachment.

able, and the polyps may be difficult to localize at the time of operation. The bowel is adequately prepared and slightly soluble sulfonamides are utilized. Spinal or general anesthesia with curare produces satisfactory operative conditions. A complete abdominal exploration is carried out. All segments of the colon are carefully explored. The segment of polyp-containing bowel is well mobilized by dividing the parietal attachment so that it may be delivered outside of the abdomen. This maneuver affords facility in palpation and makes colotomy safer. Palpation is best done with the finger passed longitudinally along the bowel and pressing back against the mesentery. The polyp-bearing segment of the bowel may be held by 4 clamps or traction sutures in the epiploic appendages (Fig 1). Frequently the pedicle of the polyp can be felt if the attachment of the pedicle is on the antimesenteric wall. When it is displaced, a dimple will appear (Fig 1).

In the absence of induration at the base, pedunculated polyps may be removed as illustrated in Figure 2. The excised specimen is examined microscopically before closure of the intestinal wounds. If induration at the base of the polyp is present or if the polyp is large and spreading, an intestinal resection with end-to-end anastomosis as illustrated in Figure 3, is indicated.

Seventy-two of the 78 patients who were treated by colotomy had polyps in the descending and sigmoid colon. In 1941, there were 2 deaths following colotomy which gave a mortality rate of 2.6 per cent; no mortality has occurred since 1941.

One-fourth of the patients who have had colotomy with removal of polyps have shown early malignant changes in the periphery of the pedunculated polyps; these changes were undetected in the frozen sections but were discovered in the permanent histologic sections. At the present time, Cattell believes that in the absence of malignant involvement of the base, local excision of the polyp will result in cure. He realizes that longer follow-up studies may change his present attitude.

Congenital polyposis continues to be a serious problem as judged by the author's experience with 23 such cases. Because of the occurrence of malignancy following subtotal colectomy with ileoproctostomy, Cattell believes that the ideal treatment is a 2-stage procedure consisting of permanent ileostomy and total colectomy including abdominoperineal resection.

ROBERT TURELL, M D

Involvement of the Ileum in Chronic Ulcerative Colitis FRED J MCCREADY, J ARNOLD BARGEN, MALCOLM B DOCKERTY, and JOHN M WAUGH. *N England J M*, 1949, 240: 119.

The ileocecal valve does not limit the progress of the lesions of ulcerative colitis into the terminal ileum. In 103 cases studied, the incidence of ileal involvement was 28 per cent. Reports in the literature vary from 13 to 39 per cent.

In the majority of cases the ileum was completely and diffusely involved in ulcerative changes similar

to those found in the colon. Occasionally, separate ulcers appear with intervening portions of the small intestine remaining essentially normal. The inflammatory reaction was much milder and far less advanced than that seen in the diseased colon. The average length of the segment of ileum affected varied from 4 to 45 cm with an average of 20 cm. The pathology was essentially denudation and ulceration.

Roentgenologic evidence of ileal involvement was found in 50 per cent of the cases in which barium enema studies were carried out.

Perforation of the ileal ulcers with generalized peritonitis was a very serious complication that occurred in 17 per cent of the cases. Obstruction of the small bowel due to stenosis of the lumen was not observed in any of the cases.

The duration of the disease showed no definite relation to the incidence of ileal involvement. Ileal involvement is not necessarily a terminal event of an intractable colitis as assumed by many authors.

Ileostomy for chronic ulcerative colitis performed through a segment of ileum that is the site of ulcerative inflammatory changes will probably produce a poor operative result. Perhaps this is one of the important considerations responsible for the high mortality associated with ileostomy in the treatment of this disease. ELY ELLIOTT LAZARUS, M D

Ulcerative Colitis LELAND S MCKITTRICK and FRANCIS D MOORE. *J Am M Ass*, 1949, 139: 201.

The problems encountered in patients with ulcerative colitis present a real challenge to both internist and surgeon. It should be recognized by physician and surgeon alike that the patient with ulcerative colitis is a strongly dependent person and that a filial devotion to the physician or surgeon may result during the treatment. Psychiatrists have clarified this point. They have brought into focus the finding that the patient with ulcerative colitis often has lost a parent, sibling, friend, or mate on whom he formerly was dependent, an event immediately preceding the onset of symptoms. This sets the stage for a physician-patient relationship of extraordinary importance in the surgical care of the disease. Recognition and acceptance of this responsibility by the surgeon permits the patient to develop dependence and affords him the relationship so essential to complete adjustment.

It is the objective of surgical management to return a patient with ulcerative colitis to society and capable of becoming a useful member of his family and community. Since ileostomy is the operation performed on a great percentage of these patients the question arises as to whether a patient with an ileostomy can adjust himself to a happy existence. Questionnaires were sent to 110 patients who left the hospital with an ileostomy, and replies were received from all patients or their families. Five patients had died natural deaths from other diseases, one patient died 2 days after an overdose of a barbiturate. Of the 104 patients whose condition was

known at the time of writing, 50 were males and 54 were females. Eighty-four per cent of these patients considered themselves to be in good health. Of the remaining 16 patients, 4 are crippled by other conditions, and 3 undoubtedly have active disease of the colon or some abnormality of the stoma which should be corrected surgically, of the 9 patients who did not become adjusted to their ileostomy, it is felt that 5 may be greatly helped by change of appliance or ileostomy outlet.

Ninety-seven per cent of the patients are working as housewives or in schools, or are gainfully employed. There is a wide variation in the types of occupation—mill workers, truck drivers, a college professor, school teachers, dentists, physicians, medical secretaries, salesgirls. Seventy-five per cent of patients felt that their earning or working capacity had not been lessened by the ileostomy. Sixty-seven per cent believed their social life to be satisfactory and not adversely affected by ileostomy. Of those who felt some limitations, 13 referred particularly to problems arising when spending the night with friends or going on camping trips, or to activities in which the lack of facilities or too intimate contact with others prevented proper attention to the ileostomy. There is, nonetheless, a surprising freedom on the part of these patients to enjoy most activities, including athletics. Twice as many of these patients are married as are single, 23 patients were married subsequent to the operation. Five patients have gone through 2 or more pregnancies subsequent to ileostomy. An understanding husband or wife, and the responsibility and satisfaction of children are undoubtedly important stabilizing factors in the lives of these patients.

Several case histories are given to illustrate the problems of ileostomy as seen by the patient. Some of these histories reflect adjustment to a new mode of life and a relatively happy existence while others indicate a morbid depression resulting from the difficulties associated with ileostomy. Its greatest difficulty applies to young unmarried girls who contemplate marriage. HAROLD LAUFMAN, M D

Idiopathic Ulcerative Colitis SIDNEY A PORTIS J
Am M Ass, 1949, 139 208

For those clinicians who raise a quizzical eyebrow whenever psychosomatic aspects of certain diseases are mentioned, this masterful article combines in a lucid and logical manner the anatomy, clinical picture, and psychiatric aspects of ulcerative colitis. Based on the proposition that emotional stimuli are transmitted over the vagus and sacropelvic nerves, the thesis is set forth that the effect of overstimulation of these nerves results in physiologic imbalance. The vagus nerve causes contraction and peristalsis of the small intestine and relaxation of the ileocecal valve as well as increased motility of the colon up to and including the transverse colon. The sacropelvic nerve has the same physiologic effect on the distal part of the colon as the vagus nerve has on the ileocecal portion.

Ulcerative colitis in its early stage is limited to that part of the colon innervated by the sacropelvic nerves. This would indicate that the altered emotional stimuli are transmitted principally over the sacropelvic nerves at the outset. It is postulated that in the early stages a protective mechanism exists in the mucous lining of that portion of the colon innervated by the vagus nerve, while the portion innervated by the sacropelvic nerves is more susceptible. After the disease progresses beyond the splenic flexure into the transverse colon, vagal influence with decreased protection may play a similar role. Recent reports that bilateral vagotomy produces definite improvement in the clinical picture of ulcerative colitis add weight to the assumption that the titer of pancreatic enzymes is a factor in this disease. Improvement following this procedure is probably due to the slowing down of peristalsis in the small intestine and first part of the colon. Neither of these portions of the gastrointestinal tract is involved in the early picture of this disease.

The early proctoscopic picture of the involved mucous membrane is similar in appearance to that of the skin about an ileostomy. This led the author to assume that increased concentration of enzyme was an important factor which produced digestion in both conditions. Liquefaction or hydrolysis of mucin is produced by mucolytic enzyme lysozyme, which is normally present in the intestinal tract and the concentration of which may change in gastrointestinal disorders. An increased concentration of lysozyme may mean lysis of mucus, and therefore an increased attack by enzymes on unprotected mucosa.

Apparently in ulcerative colitis the emotional stimuli transmitted to the rectum and sigmoid by the sacropelvic nerves produce more lysozyme than is normal for the mucous membrane of the rectum and sigmoid, and the mucous protection of the sigmoid and rectum is definitely lowered by this mucolytic enzyme. The lowered resistance of the mucous lining may allow tryptic digestion and invasion by bacteria apparently innocuous to a normally protected mucous lining. The increased peristalsis of the small intestine and colon would throw more tryptic enzyme down on an unprotected mucous membrane. Ulceration is the result of enzyme digestion. The disease process, therefore, is comparable to peptic ulcer except that it is diffuse rather than isolated. Evidence is accumulating to the effect that disturbed emotional reactions can result in ulcerative colitis.

Several case histories are reviewed to illustrate psychological disturbances which lead to abnormal bowel habits. Once the disease of ulcerative colitis is diagnosed, psychiatric management is imperative. However, psychiatric treatment should not be allowed without rigid medical control. The disease is too treacherous to be handled by the psychiatrist alone. No psychiatrist can control emotional problems 24 hours a day. Therefore, the combined man-

SURGERY OF THE ABDOMEN

agement of medical and psychiatric care is set forth as the only safe treatment.

Treatment should be directed at the eradication of the emotional stimuli, paralysis of the sacropelvic parasympathetic nerves with atropine sulfate, the abolition of influences on the hypothalamic region by the use of barbiturates, the binding of enzymes by wetting agents such as sodium alkyl sulfate, and the administration of sulfonamide drugs cautiously and only for limited periods.

HAROLD LAUFMAN, M D

Note on the Treatment of Hemorrhoids after a Few Accidents Following Sclerosing Injections (Note sur le traitement des hémorroïdes à propos de quelques accidents des injections sclérosantes) G ROUQUIER and H FUCS *Mém Acad chir*, Par, 1948, 74 649

The authors condemn the sclerosing treatment of hemorrhoids. They report 3 cases in which severe ischio-rectal abscess, necrosis, and a fissure developed in spite of the fact that the injections were given by an expert.

The authors believe that the dangerous sclerosing injections are so popular among medical men and patients precisely because the surgical treatment is improperly carried out in most hands. The authors, who have given up the Whitehead type of excision because of the high incidence of stricture, advocate a safe and simple surgical treatment. They recommend low spinal anesthesia. The first step consists in dilating the anus. This phase of the operation alone takes at least from 15 to 20 minutes and is done with the Trelat speculum. The authors point out that all instruments are rough when they are in rough hands. One must avoid tearing the anorectal mucosa. In male patients the dilatation is carried out in the transverse and oblique diameters to avoid traumatizing the posterior urethra which may cause post-operative acute urinary retention.

After the dilatation has been completed, the hemorrhoids can easily be visualized and can be collected in three or four groups. The base of each group is transfixed and tied twice with No. 1 chromic catgut. The protruding part above the ligature is excised by a live cautery. It is an important point that no gauze and no drain be put in the anus. Purgatives and enemas are used the day before surgery and opiates are then prescribed. The first bowel movement usually takes place on the sixth post-operative day. The patient is discharged on the eighth postoperative day with the instruction to take daily hot sitz baths.

GERARD GAGNON, M D

Polypoid Lesions of the Colon and Rectum A SCARBOROUGH and RUSSELL R. KLEIN *Am J Surg*, 1948, 76 723

The authors have divided polyps of the colorectum into premalignant lesions, which comprise 95 per cent of the cases, and into nonpremalignant lesions, which comprise 5 per cent of the cases. The nonpremalignant lesions include fibromas, myomas,

endometriomas, hemangiomas, granulomas, lymphoid polyps, and lymphomas. The premalignant lesions include inflammatory hyperplasias, hyperplasias, adenomas, and papillary adenomas.

The inflammatory hyperplasias, or the so-called psuedopolypoidosis, is frequently seen in patients with inactive ulcerative colonic disease. The clinical significance of this lesion resides in its ability to undergo malignant degeneration.

The mucosal inflammatory lesions are seen as multiple, pale, flattened elevations of a few millimeters in size. They are most frequently encountered in the vicinity of a carcinoma.

Adenomas vary from tiny sessile lesions to large pedunculated tumors, and may be single or multiple. Some pathologists diagnose any adenomatous polyp as grade 1 adenocarcinoma. Other pathologists diagnose malignancy on the basis of the variation in the staining properties of the cells, ballooning of the crypts, or frequency of the mitotic figures. The authors believe that such diagnoses may lead to unnecessary radical operations or a false sense of security in the safety of local excision. They believe that invasion through the basement membrane or muscularis mucosae should constitute the basic evidence of malignancy. In the presence of invasion the lesion should be called frank carcinoma and treated as such. In the absence of microscopic evidence of invasion, local excision or destruction of the polyp constitutes good therapy.

Papillary (villous) adenomas are regarded as a distinctive type of adenomatous polyp. They are extremely soft and spongy, being comprised of innumerable confluent, pliable, papillary stalks. They are rarely pedunculated but usually have a broad based attachment to the mucosa, sometimes the entire circumference of the bowel is involved for a considerable distance.

Malignant degeneration of the adenomas was found in 18 of the authors' 60 patients (30 per cent). Malignancy was demonstrated by multiple biopsies in 8 of these 18 patients. In 4 of the remaining 10 patients, malignancy was found in the surgical specimens after complete local removal. In the remaining 6 patients malignancy was suspected on the basis of induration within the soft, spongy lesion and this was confirmed histologically following radical resection. The occurrence of malignant transformation deep in the base of papillary adenomas without surface evidence of malignancy calls for complete excision or removal by means of a high frequency snare. The specimens so obtained should be scrutinized carefully for malignant foci.

In the authors' series of 458 patients, 64 per cent showed single polyps, 31 per cent had from 2 to 10 polyps, and 5 per cent exhibited diffuse polyposis of the colon. Regardless of the symptoms, every patient with a polyp found on sigmoidoscopy was accorded a competent roentgenologic examination of the colon including air contrast studies in a search for other polypoid lesions that might be situated above the region of the sigmoidoscope.

The age of the patients ranged from 5 days to 94 years. A striking infrequency of polyps in the second decade of life was observed in this series of patients.

Treatment of polyps should aim at removal of the lesion and the preservation of the specimen for microscopic examination. Tiny sessile lesions may be destroyed *in situ* by means of ball-tipped electrodes, but it should be remembered that such procedures preclude microscopy and thus may result in failure to recognize an early carcinoma. The authors have observed a poorly differentiated invasive carcinoma in a nonulcerated polyp 4 mm in diameter. Larger sessile polyps are removed with a rigid wire diathermy loop in a suitable state for microscopy. Pedunculated polyps are extirpated by means of a high frequency snare. In this series, 211 polyps in 112 patients had been destroyed by electrodesiccation through a proctoscope, while 326 polyps in 182 patients had been removed by means of a snare followed by microscopic studies of the specimens. Microscopy revealed definite malignant degeneration in 13 patients, 9 of whom had undergone a radical resection with the finding of carcinoma in the perirectal tissue or regional lymph nodes. In 4 patients local excision of long-pedicated adenomatous polyps containing small foci of malignancy had been effected. In one instance local recurrence was evident after 8 months. The remaining 3 patients have shown no recurrence in less than 2 years.

Single, grossly benign polyps situated above the reach of the sigmoidoscope were removed by colotomy in 37 patients, and histologic examination revealed malignant degeneration in 12 of them. Six of these 12 polyps had been removed by local excision without recurrence of carcinoma in a period ranging from a few months to several years following operation. The remaining 6 patients had been subjected to radical segmental intestinal resection with removal of the regional lymph nodes. The major portion of the bodies of 2 of these polyps was the seat of malignant degeneration. Although no invasion of the pedicle of any of these 6 polyps was discernible, 3 showed metastatic carcinoma in the regional lymph nodes. All 6 patients have remained well for a period of observation ranging from 1 to 8 years.

Four patients showed 2 separate polyps situated from 4 to 12 inches apart. In 1 patient both polyps were benign and were excised locally by colotomy. In the remaining 3 patients both polyps were malignant and were treated by radical resection of the segment of colon containing both polyps. In 1 of these 3 patients metastasis to the regional lymph nodes had occurred.

The authors have grouped their 31 patients with diffuse polyposis of the colon into those with diffuse adenomatous polyps and those with pseudopolyposis secondary to chronic ulcerative colitis. Among the 16 patients with diffuse adenomatous polyps there were 6 whose ages ranged from 3 to 6 years. In 2 of the latter colectomy with ileoproctostomy had been performed, similar therapy had been recommended to, but had not yet been accepted by, the parents of

the remaining 4 children. The ages of the other 10 patients ranged from 18 to 51 years. Seven of this group showed malignant degeneration, with multiple carcinomas in 5 patients. They were treated by total colectomy and permanent ileostomy. One of these patients died of recurrent carcinoma, the remaining 6 have been free of recurrence for 1 to 15 years following operation. In 2 patients without carcinoma of the rectum, colectomy and ileoproctostomy were performed following extirpation of the rectal polyps. One of these patients had required frequent electrodesiccation of new rectal polyps for more than 10 years.

Pseudopolyposis secondary to chronic ulcerative colitis was encountered in 15 patients, 4 of these patients had carcinoma, of whom 3 were inoperable. All of these patients had been subjected to total colectomy with permanent ileostomy.

One patient with chronic ulcerative colitis and polyposis extending from the splenic flexure to the rectum was treated by resection of the involved bowel with preservation of sphincteric control by pulling the transverse colon through the anal canal according to the technique of Babcock and Bacon.

The authors concurred that bleeding may occur in diverticulitis, but stated that in their experience bleeding was usually due to a coexisting adenomatous polyp. During the course of 2 years they removed polyps in 16 patients in whom rectal bleeding had been attributed to diverticulitis. No bleeding had occurred postoperatively although the diverticular disease remained unchanged. The authors believe that patients with diverticulitis and persistent bleeding which originates above the reach of the sigmoidoscope have sufficient indication for exploratory laparotomy and a thorough search for a probable polyp.

The authors also stress the proposition that extirpation of neoplastic lesions, benign or malignant, of the colon does not conclude the surgeon's responsibility, and, therefore they advocate periodic re-examinations.

ROBERT TURELL, M D

The Importance of the Level of the Lesion in the Prognosis and Treatment of Carcinoma of the Rectum and Low Sigmoid Colon JOHN M. WAUGH and JOHN W. KIRKLIN *Ann Surg*, 1949, 129: 22

From the files of the Mayo Clinic were selected the records of all patients who, in the 10-year period from 1931 through 1940, had undergone combined abdominoperineal resection for adenocarcinoma of the rectum and sigmoid colon and who had survived operation. All patients with metastatic growths in the liver or other distant sites, and, thus, those in whom the resection was purely palliative, were eliminated. The records of 453 patients were thus obtained. On careful review of the record of each patient, it was found that 65 cases were not suitable for inclusion in this study.

Three hundred and eighty-eight cases remained for study. Data were available in each case from procto-

scopic examination, digital examination of the rectum, from the surgeon's notes, and from the pathologic examination as to the approximate level of the lesion. In general, the data from these various sources agreed.

The lesions were classified according to the distance from the anal margin to the lower edge of the lesion. It is freely acknowledged that this is not a truly precise method of locating the lesions, but it has two advantages over a seemingly more precise method, namely, the measurement of this distance in formalin-preserved surgical specimens. In the first place (as noted previously) it is the most important preoperative method of estimating the level of the lesion, and in the second place there is considerable shrinkage in preserved specimens, and thus an accurate idea of the level of the lesion *in vivo* may not be obtained from a study of the preserved specimens.

It appears that the patients whose lesions lie within approximately 5 cm of the anal margin have a poorer prognosis than those whose lesions lie above this level, both groups being treated by combined abdominoperineal resection. The patients having lesions approximately 11 cm or more above the anal margin have a prognosis which is slightly better than that of the over-all group, but when there is nodal involvement the persons with high-lying lesions would seem to have a definitely better prognosis than those with either low-lying lesions or with lesions of which the lower edge ranges from 6 to 10 cm from the anal margin.

To obtain a more homogeneous group for analysis, the 248 cases in this series in which the lesions showed grade 2 (Broders) malignancy were analyzed. The data showed the same general trend as those of the entire group, but the differences were more clear-cut. The authors believe that this group represents more accurately the true state of affairs, since the lesions were histologically similar throughout the group. It was again seen that patients whose lesions were within 5 cm of the anal margin had a poorer prognosis than those with lesions lying higher up, and that those with lesions lying 6 to 10 cm removed from the anal margin had a poorer prognosis than those with lesions 11 cm or more removed from this point. Again, when only lesions with nodal involvement were considered, a location 11 cm or more removed from the anal margin allowed a much more favorable prognosis than did a lower location. In the group with grade 2 lesions without nodal involvement, the patients with low-lying lesions again appeared to have a prognosis less favorable than those with growths 6 cm or more above the anal margin.

To obtain some further information on the critical levels, as regards prognosis, the data were again analyzed, but this time the cases were put into groups at somewhat different levels.

These data again served to emphasize the relatively poor prognosis in patients with very low-lying rectal carcinomas. Thus, persons with lesions lying within 2 cm of the anal margin had, in the over-all group, a prognosis which was less favorable than

those with growths at any other level. In those with growths above this point, the prognosis gradually improved as the higher levels of the rectum were reached. It was interesting to note, in addition, that in cases with nodal involvement, the group with lesions lying 3 to 6 cm up from the anal margin had the poorest prognosis while that with lesions within 2 cm of the anal margin had only a slightly better one. The prognosis of lesions above 11 cm again was superior to that of lesions at any other level. Except for patients with lesions within 2 cm of the anal margin, in whom the prognosis was poor, patients without nodal involvement showed no significant improvement in prognosis as the higher levels were reached.

The data were similarly analyzed for grade 2 lesions only. This more homogeneous group serves to substantiate the tendencies indicated by the over-all group thus analyzed.

The failure of combined abdominoperineal resection to effect as high a survival rate in patients with low-lying lesions may well be due to its failure to cope with certain routes of lymphatic spread of the low-lying lesions. Without going into needless detail, it may be mentioned that there are, at least in theory and probably in fact, three routes of lymphatic spread in the lesions under consideration. These are, of course, (1) upward, alongside the superior hemorrhoidal and inferior mesenteric vessels, (2) laterally, along the lymphatic pathways accompanying the middle hemorrhoidal vessels and lying along the levator ani muscles, and (3) inferiorly, along lymphatics destined eventually to accompany the inferior hemorrhoidal vessels and to drain, in occasional instances, to the superficial inguinal lymph nodes.

In summary, it is nearly certain that lateral spread does occur occasionally in those far-advanced cases in which there is blockage of the superior zone of spread. It is further very probable, from the data recorded in the literature, that the spread also occurs fairly often in less extensive lesions, the lower margins of which are within 5 or 6 cm of the anal margin as estimated by proctoscopic examination, and that in point of fact in such instances, this spread, along with that in the superior zone, is the normal route of lymphatic metastasis and not an abnormal one taken only when the so-called normal routes are plugged with malignant deposits.

A Discussion on Radical Excision of Carcinoma of the Rectum with Conservation of the Sphincters G. GREY TURNER, CHARLES A. PANNETT, and O. V. LLOYD-DAVIES. *Proc. R. Soc. M., Lond.*, 1948, 41: 813.

The guiding principle in operating for cancer must always be to remove the *whole* of the affected part with a wide area of healthy tissue and the path of probable malignant invasion. It is desirable to preserve the rectal sphincters whenever this can be done.

Two types of operation "practiced very infrequently during the past 35 years" for the conserva-

tion of the rectal sphincter in carcinoma of the rectum are described by TURNER. With either the lower or posterior resection, or the anterior operation (perhaps better named "anterior resection with restoration of continuity and preservation of the sphincters") encouragingly successful long term results have been obtained, although only about 2 per cent of the patients have been considered suitable for these so-called conservative methods.

To justify consideration for these methods the growths should be small and not larger than 3.0 cm across, they should be freely movable from side to side and should move up and down when the patient strains, and there must be no evidence of dissemination. The methods are valuable also for the occasional large nonmalignant papillomatous lesions in which the circumference of the bowel is involved. Details of the operative procedures are presented. Temporary colostomy is utilized when needed. Preservation of the sphincteric apparatus must not be done unless it be combined with sufficiently radical removal of the cancer, of course.

Seventeen patients were subjected to posterior resection with preservation of the sphincters. Three were "simple" resections and 14 were for malignancies. There was no mortality, no immediate complications, and no permanent fistula or serious stricture. All of the patients had satisfactory rectal function and control. Of the 14 with malignant conditions 6 died with recurrence or dissemination within 3 years. One died without recurrence 2 years and 10 months after operation, and the 7 others either died without recurrence or were alive and well for more than 5 years after the operation.

PANNETT reviewed the errors now apparent in the Miles classic observations (of 1903) demonstrating spread of cancer downward and laterally into the ischio-rectal space, in postmortem examination of advanced cases of rectal carcinoma.

Westhues (1934), in painstaking dissection of 74 operative specimens, demonstrated that the spread of cancer of the rectum is mainly upward into the glands around the superior hemorrhoidal vessels. In only 1 specimen was there an extension 1.0 cm below the margin of the growth as seen by the naked eye. The spread in the wall of the bowel upward was a little more extensive, in the tissue behind the rectum extension occurred up to 10.0 cm, or, exceptionally, up to 12.0 cm. Lateral spread did not occur. These observations show that wide removal of tissue laterally and below the growth of the rectum as advocated by Miles is unnecessary.

In a malignancy of the rectum the growth itself should be removed with 2 centimeters of normal rectum below its margin, also 22.0 cm of rectum above the upper margin because here there may be undisclosed polypi, and all tissue behind the bowel surrounding the superior hemorrhoidal vessels upward for a distance of 12.0 cm.

LOYD DAVIES states that since the advent of the sulfonamides, and particularly sulfasuxidine and sulfathalidine, there has been a renewal of attempts at

restorative resections for cancer of the rectum and rectosigmoid.

The operative mortality in 24 abdominoanal and abdominosacral and in 30 intraperitoneal cases of resection (total 64) was 5.5 per cent. Half of these are too recent for follow-up purposes.

Following 19 radical Hartmann operations there were 6 local recurrences, this local recurrence rate of 22.6 per cent is a serious matter. Lloyd-Davies believes a local recurrence rate of 24.6 per cent is too big a price to pay for the avoidance of a permanent colostomy (the final figure may be worse since half of the patients are yet to complete the 5-year course).

Secondary excision has been done for some of these recurrences but this is always troublesome since the normal tissue planes no longer exist. In the total of 65 cases there were 16 recurrences to date (24.6%).

Lloyd-Davies believes that there should be adequate removal of tissue and division of the bowel and its mesentery at least 2 inches below the tumor, and that especial care must be taken to avoid the implantation of cancer cells. The follow up should be very close, which means rectal examination by palpation and sigmoidoscopy every 3 months and later every 6 months, and then yearly for the rest of the patient's life.

FRANK B. QUEEN, M.D.

Surgical Treatment of Cancer of the Rectum and Colon (Tratamento cirurgico do cancer retocolico)

WALTER GENTILE DE MELLO. *Rev. brasil. cir.*, 1948, 17, 37.

A historical review of the evolution of the surgical treatment of cancer of the rectum, rectosigmoid junction, and sigmoid is offered by the author.

The Miles operation, a milestone in the history of the radical treatment of the region under discussion, has recently found a competitor in form of the anterior resection, which can be performed (1) without a colostomy, (2) with a colostomy in one stage, or (3) following a defunctioning colostomy. Best results are obtained when the anterior resection is performed 14 cm above the anus or higher.

The proctosigmoidectomy with preservation of the sphincter is also widely discussed.

The simultaneous resection of other abdominal viscera involved in the malignant process is being advocated by Brunschwig, and is opening a new horizon in the concept of operability of cancer of the colon, rectosigmoid, or rectum. Four such operations performed by Brunschwig and witnessed by the author are described and illustrated.

JOSEPH K. NARAT, M.D.

Melanoeptithelioma of the Anus and Rectum. FREDERICK W. BRAASTAD, MALCOLM B. DOCKERTY, and CLAUDE F. DIXON. *Surgery*, 1949, 25, 82.

Melanoeptithelioma of the anus and rectum comprises approximately 0.25 per cent of anorectal malignant neoplasms of all types and about 1 per cent of all epitheliomatous lesions of this location. Its superficial position affords opportunity for early diagnosis, but, for the same reason, spread by the lymph

SURGERY OF THE ABDOMEN

phatics and blood vessels of both portal and peripheral systems is also manifested at an early date.

Up until April, 1947, 10 patients with this condition (including the authors'), had been seen at the Mayo Clinic.

The sex was noted in 86 of the 94 cases reported in the literature, 55 patients were men and 31 were women, a ratio of 1.8 to 1.

The age of the patients was noted in 84 instances. Seventy-six per cent of the patients were between the ages of 40 and 70, the youngest patient being 22 years and the oldest 78.

In 68 cases a sufficient description was given so that the height of the lesion could be fairly estimated. In 65 of the 68 cases the tumor was situated at, or in the vicinity of, the anorectal junction, or else in the anus itself.

These growths apparently do not tend to involve any other quadrant of the anus or rectum in preference to others. In 50 cases in which the involved wall was mentioned, the anterior wall was chiefly affected in 11 cases, the posterior wall in 19 cases, and the lateral walls (left or right) in 20 cases.

The tumors are generally single, although 14 of the 94 lesions were described as being multiple. They tend to be polypoid and to protrude into the lumen of the anus or rectum. In 19 of the 94 cases a definite pedicle was noted. The caliber of the intestinal tube is generally little affected. Ulceration has been noted occasionally.

The size of these neoplasms varied from that of small milium nodules to that of fist-sized masses. They were generally fairly small when diagnosed, probably because their low position in the rectum resulted in the early production of symptoms.

The consistency of these growths was seldom mentioned in the case reports.

Most of the patients considered their trouble to be of only a few months' duration. In the last 30 cases described, the average duration of symptoms had diagnosis was 9.2 months, in 2 cases symptoms had been present for 4 years or more and in 1 case for 2 years.

The chief complaints were those associated with a tumor in the lower part of the rectum or anal canal, namely, anal pain, stool urgency and frequency, tenesmus, "full sensation" in the rectum, or rectal discharge.

In 2 of the 94 cases the presenting symptom was enlargement of an inguinal node, and in 5 cases there were either no symptoms or only general complaints such as poor appetite, loss of weight, and so forth. Constipation was complained of in only 5 of the 94 cases.

Only occasionally did the patient show cachexia, hepatomegaly, or other signs of metastasis upon diagnosis of the rectal lesion. In a few cases the tumor had spread to involve the inguinal nodes, which were palpable clinically at the time of the initial examination.

Local examination made digitally or proctoscopically is, of course, the best means of diagnosis, and

this type of examination is seldom neglected because the patients have definite rectal symptoms. The usual diagnosis is rectal polyp, rectal polyp with malignant changes, or carcinoma, until biopsy or microscopic study of the excised lesion establishes its true nature.

Of the 94 patients, 72 (76.6 per cent) underwent surgical treatment. In 61 of these a definitive procedure, that is, removal of the tumor, was done, in the other 11 patients operated upon, either no attempt was made to remove the growth because of distant metastasis or local extension, or else the description of the operation failed to mention the type of procedure carried out. In 34 instances the operation consisted of more or less limited local removal of the growth, such as local excision, cutting of the tumor from its pedicle, cautery excision or removal of the tumor and a small part of the anus with preservation of the sphincter. In 23 cases a radical excision of the rectum was performed, consisting generally of a combined abdominoperineal operation in either one or two stages. In 6 of the former and in 2 of the latter group, roentgen or radium therapy was used in addition. Finally, in 4 cases rectal extirpation was combined with excision of the inguinal lymph nodes.

Seven of the 72 patients operated upon died immediately after operation, of the 65 who survived, 53 have been followed up. Of the 53, 36 succumbed between 1 month and 6 years postoperatively, with an average survival period of 15 months. Seventeen were living, but 9 of these 17 had a local recurrence or distant metastasis from 2 months to 3½ years postoperatively. Thus, only 8 patients were known to be living and clinically free of the disease. It is obvious that only 3 of them were followed up for such a length of time that they could be called "cured."

LIVER, GALL BLADDER, PANCREAS AND SPLEEN

Biliary Peritonitis (Peritonitis biliar) ORLANDO F LONGO *Sem med*, B. Air, 1949, 56: 103

An early interventionist himself, the author quotes Whipple on the advantages of early removal of the gall bladder while the patient is in good physical condition and before the processes of infection and their septic sequelae have had the opportunity to complicate the work of the surgeon. A number of case histories are appended. They are illustrative of the various types of biliary peritonitis (according to the classification of Niemeyer) with perforation into the free peritoneal cavity—perforations into pockets produced by the agglutinative defenses of the surrounding structures and perforations into the neighboring hollow organs.

The majority of cases of biliary peritonitis result from disease of the gall bladder or bile passages. In 1 case of free biliary peritonitis the photomicrograph of a portion of the removed gall bladder revealed that the sinuses of Rokitsansky-Aschoff were

penetrating through the muscularis under the serosa where they seemed to be the source of the free perforation. In some cases such perforation was suspected but could not be demonstrated. Cholangiography during the operation is recommended in order to detect residual stones in the bile passages or other conditions which might result in hypertension of the bile within the biliary system and subsequent rupture of the gall bladder or bile canal. In extensive gangrene of the gall bladder, the bladder must be removed, however, in other cases of severe cholecystitis it is advised to leave the bladder *in situ* with drainage to the outside in order to forestall the development of this condition, the gall bladder being removed later on.

Leakage through the intact, although possibly altered, walls of the gall bladder or choledochus, and particularly seepage from the bed of the removed bladder, as well as abscess of the subhepatic pockets are quite as fatal as general peritonitis. Brunschwig is quoted with regard to the many ways in which biliary peritonitis can result from faults or accidents of the operations for cholecystic and bile duct conditions.

The importance of abdominal puncture is cited and illustrated, together with the evil consequences which may result from the neglect of this diagnostic procedure.

JOHN W. BRENNAN, M.D.

Liver Abscesses, 44 Observations with Analyses and Statistics (Supuraciones hepáticas, 44 observaciones. Análisis y estadística) HECTOR CARDEZA
An. Fac. med. Montev., 1948, p. 749

Of 44 patients with liver abscesses, 37 (84.5%) were men and 7 (15.5%) were women. In 36 patients, (82% of the entire group) amebiasis was responsible for the condition, causing abscesses alone in 32 instances, and abscesses and hepatitis in 4. Hydatidiform cysts with secondary suppuration are not included in the author's material. In the remaining 8 cases, the infection originated in the portal system or in the appendix. In 50 per cent of all the cases the condition developed between the ages of 20 and 40 years.

Fourteen per cent of the patients with amebic abscesses and 75 per cent of those with pyogenic abscesses died, 15.5 per cent of the entire group had multiple abscesses, with a mortality of 57 per cent. Single abscesses were present in 84.5 per cent of the entire material, with a mortality of 19 per cent. Of 38 patients with liver abscesses who were operated upon, 8 died.

In 32 cases the abscesses developed in the right lobe, in 5 in the left, and in 7 in both lobes.

The acute development was much more frequent than the chronic type.

Pain, fever, and hepatomegaly were the most frequent manifestations. Leucocytosis was found in the great majority of cases but should not be considered as an infallible index of suppuration. A moderate anemia was usually present. A limitation of the movements of the diaphragm, and its elevation were

the most important roentgenologic findings. Vomiting was relatively rare but loss of appetite was frequent. Intestinal disturbances were recorded in 44 per cent of the entire group of patients. In 50 per cent of the entire group there was a partial dullness over the right lower lobe of the right lung, and diminution of the fremitus and respiratory sounds.

While an enlargement of the left lobe of the liver in patients with an abscess of the right lobe is relatively rare, suppurating hydatidiform cyst is usually accompanied by a compensatory hypertrophy of the left lobe of the liver. This observation is of importance for the differential diagnosis.

Rectal examination should be done in each case because it may reveal the primary specific lesion. Examination of the feces may demonstrate the presence of amebas.

The differential diagnosis should include the following conditions: primary cancer of the liver, cirrhosis, cysts of the liver or the pancreas, perinephritis, subphrenic abscess, cholecystitis, pleurisy, and pulmonary lesions.

In 38 patients surgical treatment was instituted, 6 were treated conservatively. The medical treatment consisted of the administration of antibiotics and emetine with due attention to correction of dehydration and malnutrition. The surgical treatment consisted of a diagnostic aspiration followed by incision and drainage. In infections caused by amebas, emetine was given preoperatively and postoperatively. The operations were performed in the majority of cases under block, and local or general anesthesia. Spinal anesthesia was used only in 4 cases. In 27 patients the abdominal, and in 8 the thoracic, approach was employed.

As a rule, amebic infection causes a single liver abscess, if the lesions are multiple, their number does not exceed 2 or 3. On the other hand, pyogenic lesions following angiocholitis or portal thrombosis are usually multiple, invading one or both lobes of the liver.

Complications were noticed in 35 per cent of the entire group, the most frequent being pleuropulmonary lesions, subphrenic abscess, hepatitis, and cardiovascular disorders.

JOSEPH K. NARAT, M.D.

Primary Cancer of the Liver Hepatoma (Le cancer primitif du foie, hépatome) J. HIRSHEN
Acta chir. belg., 1948, No. 8, 509

Primary cancers of the liver are rare occurrences. They represent only 1.24 per cent of all malignancies of the liver. They are about twice as frequent in men as in women.

The author reviews the world literature on the subject and reports in detail on 70 cases, 10 of which had not been published previously. It is interesting to note that among these 70 cases there were 8 in children under 13 years, 2 being under 1 year of age.

As to the pathologic anatomy, most of the tumors are true carcinomas originating from the parenchymatous cells of the liver. According to their manner of proliferation and the amount of connective tissue

SURGERY OF THE ABDOMEN

stroma, they are classified by most authors in three groups: alveolar, trabecular, and mixed hepatomas. The alveolar form simulates the structure of the normal liver, whereas in the trabecular form the cells grow in bands, not separated by connective tissue.

Some authors use a different classification, they distinguish between malignant adenomas which are surrounded by a capsule, primary carcinomas which infiltrate the parenchyma without forming a capsule, and the carcinomas which occur in connection with, or as a sequel of, cirrhosis.

The tumors may invade the neighboring organs by contiguity. Infiltration of the hilar lymph nodes occurs late, if ever, and metastases to distant organs are extremely rare.

Other malignant liver tumors occurring as primary growths are cholangiomas and, quite rarely, sarcomas and endotheliomas.

As to prognosis and treatment, the author does not share the pessimistic attitude of earlier surgeons; he shows that early and thorough extirpation gives encouraging results, provided that no ascites is present, and that the surface of the liver appears smooth rather than nodular (which would indicate multiple intrahepatic metastases). According to various French and American statistics, from 25 to 50 per cent of the surgical patients survived for more than 2 years without signs of recurrences or metastases.

WERNER M. SOLOMITZ, M.D.

Recurrences after Cholecystectomy (Récidives après cholécystectomie) PIERRE MALLET GUY *Bruxelles méd.*, 1948, 28, 2603

Cholecystectomy, performed indiscriminately in the treatment of gall bladder syndromes, is followed by recurrences in 30 per cent of the cases according to internists.

The author speaks only of the problem of true recurrences of pain and jaundice that occur or recur after the cholecystectomy. Since they are refractory to medical treatment, a second operation is necessary.

In certain cases, the recurrence is obviously due to faulty surgical technique with injury to the common duct.

More often the second operation reveals an obstruction unknown at the time of the first operation, such as a small calculus in the common duct, chronic pancreatitis exerting pressure on the common duct, or narrowing of the sphincter. The most common cause of recurrence after cholecystectomy, however, is dyskinesia of the sphincter of Oddi. This dyskinesia may be primary or associated with obvious anatomical lesions which alone are discovered at the first operation. It is also the author's opinion that the dyskinesia antedates the operation.

The diagnosis of dyskinesia is very difficult and more often is impossible, even during operation for recurrence, if the surgeon merely explores the common duct. In these cases the surgeon has the feeling that the operation was futile. The author believes

that the positive diagnosis of dyskinesia can be established only by roentgenographic and manometric studies of the common duct during the operation.

The author uses for roentgenographic study the method as described by Mirizzi of Cordoba, Argentina. He thinks, however, that this alone is not sufficient and has added the manometric studies. These two studies, according to the author, should be done routinely in all biliary surgery. The operation is prolonged but 10 minutes.

The author, using this technique, has performed 770 operations. Thirty-seven of the patients had had previous simple cholecystectomy. The causes of recurrence of symptoms in these 37 cases were anatomical factors alone in 9 cases, or 25 per cent—calculus (5), growth (1), stenosis (1), and chronic pancreatitis (2), functional factors only (dyskinesia) in 19 cases, or 53 per cent—hypertonicity of Oddi's sphincter (8), and hypotonicity of Oddi's sphincter (11), and both anatomical and functional factors in 8 cases, or 22 per cent.

In 1 case it was possible to confirm the integrity of the biliary tree from the anatomical and functional standpoints. The recurrence was attributed to a psychic factor.

Hypertonicity of the sphincter of Oddi was treated by vagotomy and transduodenal sphincterotomy. Unilateral splanchnicectomy was the treatment of choice for hypotonicity of the sphincter.

GERARD GAGNON, M.D.

Further Experiences with Injured Bile Ducts FRANK H. LAHEY *N. England J. M.*, 1949, 240, 161

Early in 1923 the author became interested in the problem of injuries to the bile ducts, and his first paper on this subject dealt with the results which had been obtained by the complete transplantation of external fistulas in cases in which the common and hepatic ducts had been so injured and severed that all, or practically all, of the bile was being discharged externally. This operation was first proposed and employed by Hugh Williams at the Massachusetts General Hospital, in Boston.

Since that time there has been continued interest in the problem of the management of patients with strictures of the common duct and defects in the common and hepatic ducts from excising sections of them.

Two hundred and twenty-seven patients were operated upon for benign strictures of the bile ducts. There were 27 hospital deaths in the entire series, an over-all mortality of 11.9 per cent. In 139 of these patients, the operations have been performed since 1943, with 12 deaths, a mortality for this period of 8.6 per cent. In this experience nearly every known type of surgical approach to the problem has been employed. Richard B. Cattell and the author have now developed a method that offers the best prospect of a lasting, satisfactory result in cases in which it can be employed. A report of this method will be published later in a journal devoted entirely to surgery, but it is described in the latter part of this

present article in enough detail so that any surgeon who may care to use it may do so. These strictures have varied greatly in character. The number of previous operations these patients had undergone before coming to the Lahey Clinic, varied, likewise, the measures employed in the attempt to restore the flow of bile into the intestinal tract. The lesions have been complicated and, in many cases, unsatisfactory to deal with. However, when one realizes that portal cirrhosis or failing liver function (which is due to the biliary back pressure from stricture and the superimposed cholangitis so frequently associated with this lesion) will eventually result in death in all these cases unless something is done, it can be understood that however unsatisfactory many of these cases may be, one must still endeavor to handle them surgically. This is done in an attempt to restore some of the patients to complete health, and to prolong the lives of others, making an unsatisfactory state a little more satisfactory than it would otherwise be.

In seeking for a method that offers more satisfactory prospects of restoring the excised or damaged common and hepatic ducts to normal, and thus the discharge of bile in the duodenum by a normal channel, two factors are of importance. One, outstandingly, is the necessity for preservation and function of the sphincter of Oddi. It is only by the preservation of this apparatus that one can be assured of the absence of ascending infection, chills, and jaundice, and their effect upon the liver itself. The other requirement is that permanent restoration of the main bile channels can be accomplished only by direct end-to-end anastomosis of the injured or severed duct so that there is accurate mucosa-to-mucosa approximation, as is necessary in restoration of any of the mucous membrane-lined structures in the body that convey either fluid or liquid.

In the course of a large experience with mobilization of the duodenum and demonstration of the lower end of the common duct where it passes through the head of the pancreas and into the duodenum, in connection with the surgical treatment of duodenal ulcers adherent to the bile ducts, it has been learned to mobilize the duodenum by mobilizing its external wall, and to demonstrate the portion of the common duct behind the duodenum and within the pancreas by splitting the pancreas about the common duct. By so doing, attention was directed to the possibility of mobilizing this portion of the common duct which, by its location within the head of the pancreas and behind the duodenum, is usually protected from injury no matter how many operations are done for repairs on cut or crushed ducts.

It was through familiarity with this procedure and with Cattell's experience with resections of the pancreas that the author became interested in so mobilizing the duodenum and so visualizing the lower end of the common duct behind the duodenum and in the head of the pancreas that when an adequate amount of hepatic duct stump remains, as it usually does, direct end-to-end anastomosis could be accomplished.

In doing these end-to-end anastomoses, all sorts of unsatisfactory conditions are bound to arise. An occasional condition for which the author knows of nothing that can be done, is that in which the lower end of the duct can be found but is of such small, atrophic character that it is impossible (even after it has been mobilized) to dilate it to a size adequate for the introduction of a T tube of satisfactory caliber. In still other cases there will be so much destruction and scarring of the pancreas, the common duct, and the region about the duodenum that it will—very rarely indeed, but occasionally—be impossible to find enough duct, even though it is completely mobilized, to get the ends together. Still another complication, which has been the most trying one, is the fact that often repeated, unsuccessful attempts at repair will have so destroyed the common hepatic duct that there will only be the separated intrahepatic right and left ducts. Cattell has even been able to anastomose successfully the left hepatic duct when it was impossible to find the right duct because of the depth of scarred duct within the liver. In such cases atrophy of the right lobe and enlargement of the left have taken place, with adequate maintenance of liver function. Still another complication in these trying operations has been opening of the portal vein in the course of searching for either the lower end of the duct or the end of the hepatic duct within the hilus of the liver. In these cases such bleeding has been successfully controlled by suture of the portal vein, but this has resulted in the necessity of terminating, at least temporarily, further search for the duct.

Experiences in the surgical management of 227 patients with benign strictures of or injuries to the bile ducts are presented. The development of the different methods employed since 1923 is outlined, and the disadvantages of all these measures are discussed. A new plan, which has been employed for a minimum of 5 years in 43 cases, results in preservation of the sphincter of Oddi and direct mucosa to mucosa anastomosis when it can be employed and offers, it is believed, both the most logical approach to the surgical management of this up to now discouraging lesion and the best prospect of the permanent discharge of bile from the liver into the duodenum without complications that are involved in other procedures.

JOHN E. KIRKPATRICK, M.D.

Venous Block of the Spleen and Splenomegalic Inhibition of the Bone Marrow (Venöse Blockade der Milz und splenomegale Markhemmung) ST GREIF and F. SPATH *Wsen med Wschr*, 1949, 99, 3

The authors describe 2 cases of splenic vein thrombosis in women of 16 and 44 years, respectively, in whom the leucocyte and platelet counts presented great variations which occurred during periods in which there was no gastrointestinal bleeding. In the first patient the leucocyte count ranged from 17,049 to 2,179 and the platelet count from 386,000 to 94,615, in the second patient the leucocyte count

SURGERY OF THE ABDOMEN

ranged from 16,400 to 2,946 and the platelet count from 369,000 to 93,250. In both patients leucocytosis was associated with thrombocytosis, and leucopenia with thrombopenia. Splenectomy was performed.

While before this operation the bone marrow had been normal except for irritation of its red portion in the second patient, after the operation the red marrow in both patients showed considerable division and irritation and the white marrow was myelocytic, there was an increase in the megakaryocytes. Several months later the bone marrows were normal.

In both cases the adrenalin test performed before and after splenectomy showed the same changes in the blood pictures, thus, this test as an aid in the differential diagnosis of the splenomegalies is of doubtful value, but it reduced the size of the spleens which revealed that the splenomegaly was due to stasis and not to sclerosis.

In the first case the cause of the condition could not be ascertained. In the second case the cause was a hypernephroma which had developed in the ventral direction and compressed the splenic vein.

The variations in the leucocyte and platelet counts could be explained as follows: Under normal conditions the blood from the spleen reaches the general circulation by passing through the liver where the substances secreted by the spleen which inhibit the bone marrow are neutralized or weakened. But a collateral circulation had formed in both cases and allowed the blood of the spleen to enter the general circulation directly without passing through the liver. Since an antagonistic influence between the spleen and bone marrow can be accepted, it is reasonable to think that the direct passage of splenic blood into the general

circulation would allow the substances which inhibit the bone marrow to act more intensely than under normal conditions.

The alternation between leucocytosis-thrombocytosis and leucopenia-thrombopenia, especially in the second case, was probably due to the changes in pressure exerted by the tumor on the splenic vein so that its blood reached the bone marrow sometimes over the portal system and sometimes over the newly formed collateral vessels, and in this manner the splenopathic inhibition of the bone marrow was decreased or increased.

Retroperitoneal Lymphangioma with Fistula in the Colon Demonstrated by Roentgenography
(Tumeur kystique rétro-péritonéale [lymphangiome] fistulisée dans le colon avec mise en évidence radiologique de la communication) A. LEMAIRE, H. REDON, and G. LEDOUX-LEBARD. *Mém Acad chir*, Par, 1948 74 645

The authors present a case of a female under observation for an undiagnosed mass in the upper left quadrant of the abdomen. After a fall on the street, she suffered rather vague abdominal discomfort and, later, diarrhea of brown foul material. The physician noted that the mass disappeared. Roentgenography showed a fistula between the transverse colon and the retroperitoneal mass.

At operation the mass was excised, and splenectomy and partial colectomy were done. The final diagnosis was lymphangioma of the retroperitoneal space. It is the first time, in the opinion of the authors, that a retroperitoneal cystic lymphangioma has been known to rupture into the gastrointestinal tract.

GERARD GAGNON, M D

GYNECOLOGY

UTERUS

The Roentgenogram in Uterine Malformation—With Respect to Function (Das Roentgenbild bei Missbildung des Uterus—mit Hinblick auf seine Funktion) E. PHILIPP *Geburtsh. & Frauenh.*, 1948, 8: 731

By the use of hystero-grams the author made a study of uterine malformations demonstrable by this roentgenographic means. The various abnormalities are classified into three groups: (1) uteri with a more or less divided cavity (uterus septus, uterus subseptus, and uterus arcuatus), (2) uteri with two horns (uterus bicornis), and (3) uteri which roentgenologically may appear to be unicornate but may actually have an atretic horn of a bicornate uterus. Each group is considered with reference to its likelihood of causing primary sterility, of causing abortion, and of permitting birth of a full term child.

The various types of septate uteri are the most frequently found anomalies. Recognition depends to a great extent on x-ray examination. Primary sterility is not unusual and abortion often results should implantation occur. Delivery of a full term fetus is apt to be complicated and therefore dangerous for the child. Uterus bicornis presents similar and more serious difficulties. A unicornate uterus or a bicornate uterus with an atretic horn presents a gloomy prognosis so far as childbearing is concerned.

WARREN R. LANG, M.D.

Wide Conization of the Cervix ROBERT J. CROSSEN *Am. J. Obst.*, 1949, 57: 187

The author presents an analysis of 1,021 cases of cervicitis. All patients were treated by wide conization of the cervix, and it was possible to follow 634 of the patients for 2 to 14 years. The infected portion of the cervix was removed by conization with use of the modified Crossen electrode. A wide conization was accomplished which allowed for removal of all infected tissue. Spot coagulation was applied to all bleeding areas, and the vaginal mucosa was inverted into the canal by the use of a modified Sturm-dorf suture.

Postoperative bleeding was not bothersome and occurred to a slight degree in only 11 cases. In 10 cases a single tamponade was required to stop the bleeding, and in 1 case bleeding was stopped by curettage.

Although the external os was routinely left undisturbed, stricture of the cervical canal developed in only 16 patients, who were treated in the office by dilatation, only 3 required hospitalization.

Ninety-one per cent of the patients were completely cured of the cervicitis by this method. Additional cures were obtained by secondary treatment (14 patients required reoperation, and 67 required additional minor treatment).

Sixty-three of the patients had subsequent deliveries at or near term, of these, 40 were first deliveries, following the conization. This method of treatment does not interfere with childbirth. It often removes a sterility factor, and women of childbearing age should not be denied the benefits of treatment.

Cancer was discovered in 16 cases (lesions of the cervix in 8 cases and lesions of the endometrium in 8). Curettage is routine before wide conization. Fifteen patients had further treatment for cancer and are alive and well, 1 patient who refused further treatment is dead.

None of the patients who submitted to conization has developed cancer during this period of observation.

JOHN R. WOLFF, M.D.

Malignant Tumors of the Uterine Fundus Subsequent to Irradiation for Benign Pelvic Conditions HAROLD SPEERT and THOMAS C. PFIGHTAL *Am. J. Obst.*, 1949, 57: 261

Exposure of the female genital organs to roentgen rays or radium may not be as innocuous as it has long been believed to be.

At the Roosevelt Hospital, in New York, a survey of the 270 patients who have been treated for malignant tumors of the uterine fundus revealed that at least 21 have had previous pelvic irradiation for benign conditions.

Sixteen of these patients were treated with radium, 4 were treated with roentgen rays, and 1 patient was treated with both. The radium was applied in the uterine cavity in all but one case. The radium dosage varied from 350 to 1,500 mgm/hr. The average time interval between radiotherapy and the recognition of the malignancy was 8 years, with a variation of from 8 months to 19 years. Uterine myoma was the indication for therapy in 7 cases and the curettings showed an endometrial hyperplasia in at least 6 instances.

Eleven of the subsequent lesions were adenocarcinomas, 3 were adenocanthomas, and 6 contained sarcomatous elements.

The incidence of cancer of the uterine fundus among patients who had previously received pelvic irradiation for benign conditions was 8 per cent.

In contrast, 0.3 per cent of patients with carcinoma of the cervix had received previous pelvic irradiation. The incidence of sarcoma in this group was five times that of sarcoma among all the malignant uterine tumors. The possible carcinogenic effect of radiant energy upon the human uterine fundus is suggested.

JOHN R. WOLFF, M.D.

Cancer of the Uterine Cervix (Cancer cervico uterino) ALFREDO BERNAL *Bol. Soc. chilena obst. gín.*, 1948, 13: 171

In the Gynecologic Service of the San Borja Hospital from 1942 to 1948, a slightly modified Wertheim

GYNECOLOGY

operation was used in 27 patients, usually under spinal anesthesia, and all but 3 were then sent to the Radium Institute to continue their treatment. The patients had not been well selected since several presented grade 2 and 3 lesions.

The most frequent complications were bladder paralysis (observed in 10 patients and due to trauma during the operation), and cystitis (caused by the indwelling catheter which was left in place for 24 hours to avoid repeated catheterization. Abscess of the cellular tissue occurred in 3 patients, acute bronchitis in 2, pneumonia in 3, and vesicovaginal fistula in 2. There were 2 deaths: one from pneumonia on the twenty-first day after the intervention, the other from postoperative eventration on the third day.

Some years ago the operation of Wertheim was relegated to second place because its mortality was rather high and radium therapy gave equal or superior results, but it is now again in favor because of the failures and complications of radium therapy and because of the excellent results obtained from improvement in the surgical technique, selection, and preparation of patients, and the use of antibiotics. The primary mortality of the two methods is now about the same.

In the selection of patients for operation preference must go to those under 50, of low body weight, and in good general condition, having a lesion in the first stage or going into the second stage. Nephritis and processes causing persistent leucopenia are contraindications for surgery. Spinal anesthesia is best, although good results have been obtained with ether also despite a greater number of postoperative complications. Preoperative and postoperative treatment is as important as the operation itself, preoperative and postoperative transfusions and drop transfusion during the operation, penicillin for 24 hours before and 48 hours after the intervention, and sulfonamides when penicillin is not available. The patient must be hospitalized 4 days before operation for thorough preparation.

Under these conditions the mortality should not exceed 2 or 3 per cent, and it may be further decreased to reach that of radium therapy for several reasons. Once the cervix is removed there is no possibility of recurrence, and the danger of metastasis is also eliminated. Extirpation of the pelvic lymph nodes is safer and more radical than their irradiation, and experimental work has demonstrated that the radiations do not reach the high pelvic lymph nodes.

Therefore there is the possibility that radium therapy does not provide a perfect cure. On the other hand, it sometimes causes considerable vaginal atresia and ureteral strictures. The fistulas, hepatitis, cystitis, rectosigmoiditis, and other less important complications lead the author to think that it is best to continue operating on these patients, in doubt, so the conclusion will soon be reached that Wertheim's operation is not a dangerous intervention.

The Value of Postoperative Irradiation of Cancer of the Uterus (Ueber den Wert der postoperativen Nachbestrahlung des Uteruskarzinoms) HEINZ KIRCHHOFF *Geburtsh & Frauenh*, 1949, 9 17

There is no unanimity of opinion as to the value of postoperative x-ray treatment of cancer of the body and cervix of the uterus. The opponents maintain that the inflammatory processes in the operative region diminish the radiosensitivity of the cancer cells and increase the resistance of the body. Irradiation lowers the resistance of the body.

From a review of all available statistics, Schinz found that a 5 year cure was recorded in 41 per cent of patients who underwent operation without postoperative treatment, while of those who were irradiated after the operation, 55 per cent remained cured after 5 years, however, the patients in these 2 groups were not always treated at the same time so that a comparison is subject to criticism. For instance, such factors as changes in the surgical technique and indications for the operation, the performance of the operations by different surgeons, postwar conditions affecting nutrition, etc., may influence the results. Furthermore, the selection of material for irradiation is an important factor. Some surgeons leave the ovaries *in situ*, in young patients. The obscure relation between the genesis of cancer and endocrine factors may cloud the results of irradiation in such instances.

The author presents a plea for careful statistics over a period of 10 years, in order to form a definite opinion as to the value of postoperative x-ray treatment of cancer of the uterus.

JOSEPH K. NARAT, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS
Gynandroblastoma of the Ovary JOHN E. HOBBS
Am J Obst, 1949, 57 85

An 18 year old girl was operated upon by the author for the removal of a large ovarian tumor which contained both masculinizing and feminizing morphologic structures. This rare tumor was named gynandroblastoma by Robert Meyer in 1930, and, to date, 21 such cases have been reported.

The clinical features of the present case suggest the hormonal effects of androgens and estrogens. The primary tumor showed a predominance of androgens from a biologic consideration, since there was masculinization and defeminization. Amenorrhea, hirsutism, and hypertrophy of the clitoris were present. A study of 17-ketosteroid excretion has not been of value.

After removal of the tumor, and even though it has repeatedly recurred, there has been no biologic or histologic evidence of androgen elaboration, while there has been clinical evidence of estrogen production.

Three further operations were necessary because of recurrence of the tumor. X-ray therapy undoubtedly slowed the growth of the tumor, but was not lethal even in large concentration.

RICHARD KEMEL, M.D.

Histologically, this type of tumor lacks most of the criteria for malignancy, yet it is recurrent and locally invasive

JOHN R. WOLFF, M.D.

MISCELLANEOUS

Vascular Congestion and Hyperemia HOWARD C. TAYLOR, JR. *Am J Obst*, 1949, 57, 211

Every part of the reproductive tract is subject to characteristic disturbances in vascular function, manifesting themselves in the form of arterial dilatation, venous engorgement, and probably local increase in extravascular tissue fluids. This vascular disorder results in pain in the breasts, ovaries, and parametrium, hypersecretion from the cervix, and menstrual anomalies.

Independent observers have believed that for each organ of the reproductive tract there could be distinguished an early phase of congestion leading to a later one of fibrous tissue. That such a pathologic process should result under conditions of prolonged vascular stasis is entirely possible.

Since manifestations of the syndrome of congestion fibrosis in one segment of the reproductive tract are commonly found associated with signs and symptoms of the disorder elsewhere, this process must be regarded as one which is often generalized throughout the reproductive system.

Patients having symptoms of congestion of the genital tract are found characteristically to suffer from emotional instability, radiating neuralgic pains, and symptoms such as palpitation and indigestion. These associated nervous phenomena indicate a strong autonomic factor in the syndrome.

JOHN R. WOLFF, M.D.

Surgical Treatment of Genital Prolapse (Tratamento cirúrgico do prolapso genital) F. VICTOR RODRIGUES. *An Brasil gin*, 1948, 26, 365

At present surgical treatment is the only logical treatment of genital prolapse. The contraindications are solely cachexia, terminal disease, and such an advanced age that the survival will probably not compensate the patient for the trouble of the operation. The correction of other associated defects (colpocele, rectocele, enterocele, and urethrocele) and observance of the principle of interposition are absolutely indispensable in order to obtain satisfactory and definitive results.

From December 15, 1938 to July 31, 1948, the author has operated in 82 cases of prolapse, including 1 urethrocyстоcele, 2 cystoceles without uterine prolapse, 25 partial prolapses, and 54 total prolapses. The associated lesions comprised 1 each of vesicovaginal fistula, rectal prolapse, and total perineal rupture, 4 enteroceles, and 8 rectoceles. Fothergill's operation was used in 53 cases, Mayo's vaginal hysterectomy in 17, Halban's operation in 6, Bissell's operation in 2, and the operation of Le Fort, that of Spalding Richardson, and the interposition of Schauta Wertheim Watkins in 1 case each. Inhalation anesthesia was used in 6, and

local anesthesia in 76 cases. There were 4 postoperative local infections, 2 being pyometria, there were no deaths and, so far as is known, no recurrences.

The immediate results of operation were very satisfactory. Late results were observed in a patient who previously had undergone a Fothergill operation and was submitted to abdominal hysterectomy for fibroma. The uterus was found to be firmly anchored by fibrous adhesions to the anterior part of the pelvis and to be in anteversion. The cases of postoperative infection occurred before the advent of modern chemotherapy. Recovery after operation was usually uneventful.

The author is firmly convinced of the enormous advantages of local infiltration anesthesia, for which he uses a 1 per cent solution of novocain with adrenalin; he uses it in all cases in which there is no contraindication, the most common of which is hypertension. It facilitates dissection and decreases bleeding, leaving a clear field of operation. It constitutes one of the greatest advances made in the surgery of prolapse and reduces the risk practically to nil so that help can be extended to patients of the most advanced age in whom the anesthetic risk is much more to be feared than the operative risk.

Fothergill's operation has been performed under local anesthesia without any inconvenience in many patients between 70 and 80 years of age, and vaginal hysterectomy has been done in several patients over 60 and some over 70.

Of the numerous operations recommended, the author prefers those of Fothergill and of Mayo. With the discriminating use of these two methods it is possible to correct and cure all genital prolapses and to avoid recurrences. The question is which of the two methods should be used in a given case. The fact that the prolapse is total constitutes no contraindication for Fothergill's operation. The decision depends upon the condition of the uterus. Whether the uterus be very large or very small, if it presents greater possibilities of cancer because of age and associated conditions, it should be extirpated by the Mayo method. In young women who desire children, the condition of the uterus is taken into consideration and an effort is made to preserve it by using the Fothergill method. The presence of enterocele or hernia of the pouch of Douglas suggests the advisability of hysterectomy, which will facilitate correction of the defect. Fothergill's operation offers no disadvantages except perhaps that it is not the best method to use for patients with a rather small uterus.

The abdominal route is unjustifiable for the surgical treatment of prolapse. The damaged structures which require repair are all found below the peritoneum and, in case it is necessary to remove the uterus, prolapse of this organ facilitates its extirpation by the low route.

RICHARD KEKFL, M.D.

The Significance of Abnormal Menopausal Vaginal Smears H B DAVIDSON, E L HECHT, and R. L. WINSTON *Am J Obst*, 1949, 57 370

In a study of 378 apparently well women of menopausal age, the vaginal smears of 12 (3.16 per cent) presented a disturbing picture. In this group the smears had a marked resemblance to those in cases of proved cancer.

The cells vary in shape and form, and in many instances tend to form dense groups with considerable overlapping and overcrowding. In some cells the nuclei are large in relation to the size of the cell. These nuclei are bizarre in shape and often hyperchromatic. Nucleoli are often conspicuous. Vacuolization of the cytoplasm is often clearly evident. Elongation of the cells is frequent.

Such cellular patterns ordinarily satisfy the criteria for malignancy in the vaginal smear, yet biopsies have repeatedly been negative. Clinical examination has failed to detect any sign of malignant disease.

Are such smears indicative of latent cancer, or are they merely benign findings of no apparent significance? The interpretations of such smears must be made by only adequately trained personnel. Only a vast experience over a long period of time will prove whether or not these smears indicate the presence of true cancer.

JOHN R. WOLFF, M D

The Modifications of the Rectal Mucosa in Cancer of the Uterine Cervix (Sulle modificazioni della mucosa rettale nel cancro del collo dell'utero) PAOLO BORTOLUCCI *Riv ital gine*, 1948, 31 412

The material studied consisted of 61 cases of cancer of the uterine cervix. Of these, 18 cases were grouped, by the usual methods of classification, as belonging to grade 1, and 6 of these were classed, according to the subdivision of grade 1 as proposed

by Schmitz, as being in the initial stage, 26 were classed as of grade 2, 15 of grade 3, and 2 of grade 4. The rectoscopic findings of those in grade 1 consisted of localized edema and vascular dilatation in the lowermost section of the rectal mucosa. The findings of those in grade 2 consisted, as a rule, of a more marked edema and vascular ectasis than those seen in grade 1, and these were accompanied by bullae and hemorrhagic patches. The section of the rectal mucosa which was involved was the middle region of the rectum and particularly the valve of Koblrausch. In the grade 3 cases the entire extent of the rectal mucosa was apt to be involved, the changes were even more pronounced than in the two previous groups, and the mucosa was covered by a whitish exudate on the anterior surface in the region of the middle valve (Koblrausch). In the more advanced cases of this group there could be observed an extensive infiltration of the rectal wall, partially or totally encircling the bowel.

In the 2 patients with grade 4 cancer, who, of course, were inoperable, the findings rectoscopically were those of marked thickening of the mucosa, notable congestion of the blood vessels, and patches of ulceration. In some places the mucosa in these advanced cases was smooth, elevated, and thickened with complete disappearance of the normally observed plicae.

The author believes that since the malignant process in the cervix usually tends to disseminate backward toward the rectum even sooner than forward toward the bladder, rectoscopy will afford more valuable information concerning the stage of development and spread of the neoplastic process and its eventual operability than will cystoscopy. It will be of some value even in the inoperable cases (grades 3 and 4) in adjudging the efficacy of, and the best manner of applying, irradiation therapy.

JOHN W. BRENNAN, M D

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Conservative Treatment of Placenta Previa W G MILLS *Brit M J*, 1948, 2 896

The difference of opinion in regard to the management of placenta previa hinges mainly on the optimum timing of intervention. Although it is almost standard practice to actively intervene in the presence of placenta previa, some evidence is accumulating to indicate that this is not always necessary, and certainly (in some cases) not advisable.

Recent literature is reviewed and statistics are presented with regard to the fetal and maternal loss under both types of management. One hundred patients were treated conservatively. When bleeding occurred before the thirty-seventh week, the cervix was examined with a speculum and the patient was then treated expectantly. After the thirty-seventh week, depending on the size of the baby, the patient had a sterile pelvic examination, at which time the type of delivery was selected. As a rule, if the placental margin was at the rim of the cervix, or across the opening of the cervix, cesarean section was then the method of choice. If the placenta was higher than this, vaginal delivery was attempted.

The maternal mortality was apparently not increased by conservative management, and in no case was there a death or near death. The fetal loss was 16.5 per cent, which is not great if one considers other series in which the loss ran as high as 54 per cent. The disadvantages of this type of treatment can readily be seen since the mother must be confined to the hospital or to her home for a considerable period of time and may, from time to time, have repeated hemorrhages requiring transfusion. The main advantage would seem to be the improved fetal prognosis, due largely to the increase in size and maturity of the infant. Obviously, this type of management can be carried out only when suitable hospital facilities, including a blood bank, are available.

JAMES F DONNELLY, M D

Facts Pertinent to a Rational Concept of Abruptio Placentae R A BARTHOLOMEW, E D COLVIN, W H GRIMES, JR, and JOHN S FISH. *Am J Obst*, 1949, 57 69

That abruptio placentae is a manifestation of toxemia of pregnancy and, as such, is a phenomenon which may occur in any case of severe toxemia and interrupt the pregnancy before the convulsive stage is demonstrated by clinical and pathologic evidence.

The signs and symptoms of toxemia often precede abruptio placentae. Abruptio placentae and toxemia occasionally occur simultaneously, the findings at autopsy are often identical. Acute and subacute hemorrhagic placental infarction is present in both.

The sequence of events, initiated by a spasmogenic factor (pituitary and/or renal) on the sphincters of

the placental veins is that of (1) obstruction to the outflow of fetal blood from a dependent unit of placenta, (2) distention, thrombosis, or rupture of the villous vessels with resulting enlargement and crowding of villi, (3) diminution of maternal blood and absence of fetal blood supply to villi from crowding and thrombosis, and (4) dissemination of the poisonous products of the resulting placental necrosis with the development of signs and symptoms of toxemia. True toxemia may be gradual, through stages of mild, moderate, and severe, or may be fulminating. Severe toxemia may terminate in (a) abruptio placentae, (b) eclampsia, and (c) eclampsia. Occasionally abruptio placentae and eclampsia occur together.

Renal and vascular disease are not true toxemias but are predisposing causes probably through a spasmogenic factor which may cause overaction of the sphincters of the placental veins with resulting placental infarction.

JOHN R WOLFF, M D

Pregnancy and Hodgkin's Disease S CHARLES KASDON *Am J Obst*, 1949, 57 282

Since Hodgkin's disease as a complication of pregnancy is uncommon (1 case in 6,000 pregnancies), a rational basis for the management of this problem is decidedly difficult. Three such cases seen at the Tumor Clinic of the Boston Dispensary, Boston, Massachusetts, together with 29 previously reported cases are analyzed.

Hodgkin's lymphogranulomatosis does not grossly affect ovulation, fertility, incidence of spontaneous abortion, antepartum, intrapartum, or postpartum hemorrhage. Similarly, the pregnancy does not appear to influence the course of this disease. The obstetric aspects of gestation, parturition, and the puerperium are not affected by coincidental Hodgkin's disease.

Three reports have appeared in the literature of infants with Hodgkin's disease who were born of mothers possessing this condition. Although this incidence is low, the possibility of placental transmission of the disease must be remembered. There is no report of injury to the shielded fetus from roentgen radiation used in the treatment of Hodgkin's disease.

Interruption of pregnancy during the course of Hodgkin's disease is not indicated from the evidence at hand.

JOHN R WOLFF, M D

Pregnancy Complicated by Diabetes Mellitus II H FOURACRE BARNES and M E MORGANS *Brit M J*, 1949, 1 51

Fifty-eight pregnancies in 45 patients with complicating diabetes mellitus were observed during a period of 20 years in the University College Hospital. These cases are reviewed and compared with concepts developed by a review of the literature.

In the majority of patients carbohydrate tolerance diminished as pregnancy progressed, but in some it increased prior to delivery and it was thought that estrogens given therapeutically may have been a factor in this improvement.

The authors support the view that hydramnios is more common in these patients, 29 per cent of their patients showed this phenomenon. Hypoglycemia and coma were more common in early pregnancy while ketosis and diabetic coma were more common in late pregnancy. They confirm the belief that toxemias are more common in diabetic patients, but state that the increased rate depends upon what statistics are used in making the comparison.

The danger to the mother is not great if adequate diabetic management is instituted, and the diabetes does not seem to become more severe if it is well treated.

The authors discuss the cause of the high fetal mortality. They disagree somewhat with current views, and it is their belief that the causative factor may be in the maternal anterior pituitary gland. The abortion rate was no higher in their patients than in other patients.

Babies of diabetic mothers are larger than normal, but those born to these mothers in the prediabetic state are also large, therefore, it is believed that the condition is not due to hyperglycemia but to the abnormal hormone picture with high serum gonadotropin, low serum estrin, and diminished pregnandial excretion. They suggest there may be an excess of growth hormone present.

BYFORD F. HESKETT, M.D.

LABOR AND ITS COMPLICATIONS

Investigations on Prolonged Pregnancy (Untersuchungen ueber den Partus serotinus) MIES REEN KOLA. *Acta obst. gyn. scand.*, 1948, 28 Supp. 3

The author reports his studies on all cases of partus serotinus (prolonged pregnancy) occurring at the University Clinic of the Public Hospital in Helsinki during the period from 1917 to 1944. Included in the series were women whose pregnancies had lasted more than 300 days counting from the first day of the last menses. Women who had irregular menses before pregnancy and who were not exactly certain of the last period were also included. There were 507 primiparas and 379 multiparas, but the latter included only those observed from 1930 to 1944. The weight or length of the infant was not used as a criterion of postmaturity.

In comparison with the other parturients, the menarche occurred late and the menstrual cycle tended to be irregular. Oligomenorrhea was not a statistically significant finding, however. The body build of the patients often approached the infantile variety, with a small pelvis and most frequently of the generally contracted variety. There was no unusual incidence of toxemia in the group studied.

The average infant weight was high, however, the lower limit was not significantly greater than

the lower limit of normal infants. The same observation applied to the length. There was no correlation between the duration of pregnancy and the weight or length of the infant. The placental weight followed a similar pattern.

Labor was often prolonged. This was particularly noticeable in the first stage, less so in the second. Rupture of the amniotic sac occurred later than usual. Abnormal positions and presentations were found infrequently and operative delivery (instrumental or by cesarean section) was resorted to on relatively few occasions.

The infant prognosis was directly related to the factor of operative intervention. There was some evidence that some babies died from unknown causes before birth. In fact, about 0.6 per cent of the deaths were thought to be the result of the prolonged pregnancy itself. The author describes 2 cases personally followed up by him during pregnancy in which the infants born were below the average in weight.

The author concludes that one of the principal factors in the etiology of prolonged pregnancy is a weakness of the genital constitution as manifested by either primiparas or individuals with infantilism. Many causes, however, are as yet undetermined.

WARREN R. LANG, M.D.

Internal Podalic Version and Extraction HENRY W. ERVING. *Am. J. Obst.*, 1949, 57: 333

Although internal podalic version and extraction is an obstetric procedure hallowed by time, its value is often overlooked. This may be due to the consternation and controversy which has been caused by the proponents of routine version.

In three and one-half years, internal podalic version and extraction was utilized to deliver 534 babies (frequency of 4.1 per cent) at the Elizabeth Steel McGee Hospital, in Pittsburgh. The majority of these patients were of private status and all were delivered by or under the supervision of obstetricians.

The main indications were inertia, failure of descent, transverse arrest, and persistent occipitoposterior position. Prophylactic version was done mainly for the second twin, and in multiparas with completely dilated cervixes, having poor pains and with the head of the fetus high in the pelvis.

In almost one-half of the cases the membranes were ruptured from one-half hour to 5 days prior to delivery. Premature rupture of the membranes does not contraindicate a version. The tonus of the uterine musculature and displacement of the head are the important criteria.

There was 1 maternal death (without autopsy), the uterus was ruptured in 1 instance, third degree lacerations of the perineum occurred seven times, and physiologic retraction rings were noted 26 times.

Gentleness and the rigid adherence to contraindications will prevent complications. These latter are marked cephalopelvic disproportion, true constriction ring dystocia, a dry uterus molded about the child, incomplete dilatation and effacement of the cervix, previous section or myomectomy, placenta

previa, an inexperienced anesthetist, and insufficient help

The gross infant mortality was 5.8 per cent, corrected 2.6 per cent. Forceps to the aftercoming head along with routine episiotomy are recommended. An android pelvis is dangerous with regard to infant mortality.

Internal podalic version and extraction is an important method of handling a difficult obstetrical situation and more men should be adequately trained in the performance of this procedure.

JOHN R. WOLFF, M.D.

Management of Occipitoposterior Position GER-
ALD W. GUSTAFSON *J Am M Ass*, 1949, 139
280

The author divides occipitoposterior positions into three groups as far as management is concerned. In the largest group, which comprises some 70 per cent of the total, rotation will occur spontaneously after engagement, and with comparative ease in delivery either spontaneously or with low or midforceps. This group, he believes, can be increased by conservative management.

The second group is small and comprises those cases in which some pelvic contraction or disproportion is usually present so that even after hours of labor, engagement does not occur. In some of these cases engagement occurs after the second stage of labor is reached and they can then be classified in the first group, still others may be classified in the third group, and in some abdominal delivery will be necessary.

The third group comprises those cases in which engagement occurs, but there is failure of rotation in the so called persistent occipitoposterior position. It is in the handling of these cases that there is the greatest difference of opinion regarding their management, and this group may be large or small, depending on whether the operator is radical or conservative.

Various types of delivery are employed, viz., the Barton forceps, Kielland forceps, version extraction, Bill's modified Scanzoni maneuver, key and lock forceps rotation, and manual rotation.

The cause of occipitoposterior position is discussed, and the author states that many times the position occurs in borderline pelvis, especially of the android type with a narrow fore pelvis, or in those with inlet, midplane, or outlet contraction. The position is common with the syndrome of dystrophy dystocia, and it is frequently observed in the anthropoid pelvis. Other factors may be traumatic contractions, tumors, poor uterine action, and increased pelvic inclination.

The incidence of occipitoposterior position varies with many factors—especially the time of examination of the patient, and whether labor is early or late, as in many cases the position is rectified after the onset of good labor. The author reports an incidence of 3.6 per cent of persistent occipitoposterior positions. An additional 17 patients had cesarean sections. Labor was frequently prolonged, and in some cases

irregular pains preceded the labor. In many cases rupture of the membranes occurred.

Watchful expectancy with careful examination of the pelvis, including x-ray pelvimetry, is stressed. It is believed that the diagnosis of station is of utmost importance in the management of this condition.

Proper sedation and hydration is discussed. The author believes that a longer second stage of labor is permissible in patients with this complication. If interference is indicated by the condition of the baby when the head is at -1 station, he believes version to be safer than forceps.

The technique of manual rotation is discussed. The author favors this method of rotation and applies forceps in the anterior position following rotation.

BYFORD F. HESKETT, M.D.

Cesarean Section in Dublin J. K. TEFNEY *Irish J M Sc*, 1948, Ser. 6, 755

The author presents considerable statistical information with regard to cesarean section as it is practiced in Dublin, Ireland. The analysis is based on 45 annual reports of the Coombe, National Maternity, and Rotunda Hospitals. A total of 108,140 patients were delivered in these hospitals during the years from 1932 to 1946, inclusive. In this group, 2,273 cesarean sections were performed, of which 1,415 were primary sections and 858 were repeat sections. The incidence of section was 2.1 per cent and the maternal mortality was 2.7 per cent, with a fetal mortality of 11.4 per cent. Various techniques of operation were carried out, although operation on the lower uterine segment was performed in 77 per cent of the cases.

There were 61 maternal deaths, 17 of which were due to infection, 8 deaths were ascribed to hemorrhage and shock, 9 to toxemia, 10 to pulmonary complications, 2 to anesthesia, 11 to heart disease, 3 to tuberculosis, and 3 to other causes. Brief case histories of the maternal deaths are presented, and the author concludes from his analysis of these that the mortality rates could be greatly reduced.

Careful prenatal care should result in early recognition of the need of cesarean operation and immediate hospitalization. A careful review of the indications and contraindications should be considered in each case prior to the operation. This should include the proper selection of the anesthetic agent, or, as the author has put it so well, "the anesthetist." From a technical point of view, the wider use of a low segment operation, early amputation, and the modern techniques of combating shock, hemorrhage, and infection, should result in lower mortality rate.

It was difficult, from the table, to determine the exact cause of fetal mortality, since in nearly all cases the fetal death was attributed to a maternal disease and it was impossible to separate such causes as asphyxia from prematurity, since there was no indication as to the size of the baby. In addition to special pediatric care, the means of reducing fetal mortality associated with cesarean section are the same as

those used for the mother The indications for cesarean section are listed and cases are divided into primary and repeat sections

	Primary Per cent	Repeat Per cent
Disproportion	52.6	87
Placenta previa	12.5	0.6
Toxemia of pregnancy	11.0	0.9
Functional disorders of uterine action	6.2	1.6
Tumors and other causes of obstruction	3.8	1.7
Maternal and fetal distress	2.9	
Heart disease	2.9	1.3
Ruptured uterus	2.0	1.9
Age	2.0	
Previous gynecological operations	1.6	
Abnormal presentation	1.5	
Miscellaneous	1.0	4.5

The remaining cesarean sections not listed among the repeat sections were probably indicated on the basis of a previous section

An urgent appeal to reduce the incidence of cesarean section is made to the obstetrician as well as to the general practitioner, in view of the fact that the maternal mortality varies between 1 and 7 per cent, and the fetal mortality between 5 and 20 per cent. The author considers that the most important factor in reduction of the mortality rate was well expressed by Bourne when he said "As time passes (in the acquisition of experience) the actual operation, while always able to hold our attention, gradually begins to take second place in the general survey and treatment of the case. One of the characteristics of the mature and experienced surgeon is the greater importance which he attaches to the preparatory consideration of the diagnosis and to the choice of the particular operation which will be most calculated to ensure the maximum benefit to the patient, both immediately and in the more distant future."

The author concludes, from the analysis of these statistics, that (1) premature induction of labor be given a trial in selected cases of contracted pelvis, (2) that test labor be conducted only under hospital conditions, (3) that a conservative method of management of placenta previa be followed, (4) the employment of cesarean section in toxemia should be considered only in cases which do not respond to conservative therapy, (5) that most patients with heart disease withstand pregnancy and labor without difficulty, (6) that obstructing tumors should be displaced or removed, and (7) that manual correction of abnormal cephalic presentation and other vaginal procedures should be used for abnormal cephalic positions

JAMES F. DONNELLY, M.D.

PUERPERIUM AND ITS COMPLICATIONS

The Third Stage of Labor: A Plea for Manual Removal of the Placenta ROBERT A. CACCIARELLI
Am J Obst, 1949, 57, 351

The third stage of labor has repeatedly been the subject of much discussion and dissension, yet it is

the least understood, the most ill-managed, and the most tampered with stage. The persistence of postpartum hemorrhage is due to mismanagement of the third stage, and most deaths are preventable.

Immediate manual removal of the placenta makes the operator the master of the third stage and not merely a timid observer. This immediate surgical management of the third stage of labor, done under aseptic conditions in the already anesthetized patient, has reduced the incidence of postpartum hemorrhage, kept blood loss at a minimum, and has enabled careful exploration of the uterus.

A total of 1,625 cases were managed in this radical fashion without mortality. There was a morbidity of 4.6 per cent, although in no instance did the procedure itself appear to be responsible for the morbidity. Inversion of the uterus did not occur and uterine tamponade to control bleeding was necessary in only 3 cases. None of the patients required blood transfusions for postpartum hemorrhage.

The procedure of manual removal of the placenta has been unfairly condemned because the unfavorable results have been measured by the worst emergencies for which it is undertaken. It is still notoriously bad when performed upon the shocked and exsanguinated patient. In the hands of men properly trained, immediate routine manual removal of the placenta in an anesthetized patient is a safe practice.

JOHN R. WOLFF, M.D.

Chronic Appendicitis in the Puerperal State (L'appendicite cronica nello stato puerperale) FULVIO CONCETTI *Riv ostet gin*, 1947, 2, 390

An analysis of 33 cases of appendicitis during pregnancy and the puerperium, of which 31 were of the chronic or interval type, indicates that acute appendicitis is exceedingly rare during the postpartum period, and that the chronic appendix which may become manifest is the result of hormonal and mechanical factors operating upon a pre-existing inflammation. The re-exacerbation of such chronically affected appendices was found to occur with greatest frequency in the second month of pregnancy and in primiparous women.

EDITH B. FARNSWORTH, M.D.

NEWBORN

Hemolytic Disease of Newborn P. L. MOLLISON and MARIE CUTBUSH *Brit M J*, 1949, 1, 123

This article deals primarily with the criteria for determining the severity of hemolytic disease of the newborn at birth. The authors state that the presence of the disease at birth can be determined by the Coombs test but that other criteria are needed to determine its severity and whether treatment is needed.

Various tests were performed, some on normal infants, for comparison. Cord blood was collected at birth, and venous blood was tested several hours after birth. In some infants the cord was clamped immediately at birth and in others it was left untied for 5 minutes. Capillary samples of blood were taken

on the first day of life along with simultaneous venous samples. Venous pressures were measured and bilirubin values determined.

The authors believe that the various types of hemolytic disease of the newborn, from congenital anemia through icterus gravis to hydrops fetalis, blend so gradually that other criteria are needed for early diagnosis and treatment.

In their opinion, diagnosis of the severity of the disease by antibody titre is not too reliable. They do believe, however, that accurate hemoglobin determinations in cord blood offers a satisfactory criterion of the severity, and that knowledge of this value enables one, within limits, to give a reliable prognosis. Infants with a hemoglobin value of 0.8 gm per cent or less are likely to die within 24 hours of birth. These infants often show a raised venous pressure and probably die from cardiac failure. Infants with 14.5 gm per cent or over are likely to recover without treatment.

The hemoglobin values determined after birth are more difficult to interpret because of the placental transfer of blood, and the large capillary and venous differences in the newborn.

Cord plasma bilirubin determinations alone are of little value, but when compared to cord hemoglobin tests a better index to the severity of the disease is obtained.

Nucleated red cells were present in all moderately severe cases and were a striking feature of the fatal cases, while in mild cases these forms were within normal limits.

The amount of free Rh antibody in the infant's circulation, and the strength of the Coombs test are of very limited value in determining the severity of the disease. The form of Rh antibody predominating in the mother's serum and the antibody titre show some correlation with the severity of the hemolytic process in the infant.

The authors' findings emphasize the importance of determining the hemoglobin and bilirubin values of cord blood as a means of grading cases of hemolytic disease of the newborn. It is not only a help in deciding on the correct treatment, but is of value as a method of comparing one series with another.

BYFORD F. HESKETT, M.D.

Results of Therapy of Erythroblastosis with Exchange Transfusions. ALEXANDER S. WIENER and IRVING B. WEXLER. *Blood*, 1949, 4: 1.

In previous articles, the authors described the method of treatment of erythroblastosis fetalis with exchange transfusion, and presented a few illustrative cases in detail. The purpose of the present article is to summarize their results in the first 28 cases.

The rationale of this method of treatment is outlined as follows:

According to the authors' concept of the pathogenesis of the disease, in a typical case, the Rh positive erythroblastic baby is born with its red cells coated with univalent Rh antibodies derived

from the mother during intrauterine life by transplacental filtration. In some cases, it is possible that the Rh antibodies of the "bivalent" type (agglutinins) may be milked into the fetal circulation by the uterine contractions during labor. These antibodies may cause the infants' red cells to hemolyze or clump. Simple Rh negative blood transfusions suffice in the hemolytic anemia which develops from hemolyses. Clumping, on the other hand, may be more dangerous to vital organs and, in these, simple transfusions are not enough. Intravascular clumping, when it occurs, probably starts after birth, usually when the conglutinin content of the blood rises, and may be considered to be reversible at first (sludged blood). The authors believe that if the infants' blood can be drawn off early and replaced by Rh blood of a compatible blood group, this clumping can be aborted, because type Rh cells cannot be clumped by Rh antibodies in the babies' body.

The bleeding and infusion must be done simultaneously. As the exchange progresses, it becomes less efficient because more of the donor's blood is drawn off and less of the infant's. Various amounts of blood were used. With 500 c.c. of blood, 87 per cent of the babies' blood was withdrawn. With 1,000 c.c., 98 per cent replacement was effected.

The Rh should be determined on all pregnant women. If the patient is Rh negative, the husband, children, and husband's family should be tested. The maternal serum should be tested for presence of antibodies or their titre during pregnancy by the saline agglutination and albumin plasma conglutination techniques.

Women showing no sensitization are allowed to go to term, mildly sensitized women are allowed to go to term, and the infant is watched for evidence of anemia, jaundice, or signs of erythroblastosis. Moderately sensitized women are delivered 2 weeks early and the babies are immediately treated by exchange transfusion of 500 c.c., more severely sensitized women may be delivered even earlier, the babies being treated with 1,000 c.c. of blood. In severely sensitized women the babies rarely reach viability.

The authors discuss the Rh typing and antibody tests in great detail. The agglutination method, the albumin plasma conglutination method, and the blocking technique are described.

What the authors describe is a simple technique of exchange transfusions has been devised. They do not wait for tests on the babies' blood but take samples for later testing unless the father is heterozygous, in which case they wait for tests. A 20 gauge needle in the sphenous vein at the ankle is used for the infusion, and a 3 way stop cock allows for changing the speed of the infusion and also for the giving of medication directly into the cannula. First 0.2 c.c. (200 units) of heparin is injected and repeated after 250 c.c. of blood have been given in the 500 c.c. transfusion, or after 500 c.c. of blood have been injected when an 1,000 c.c. exchange transfusion is given.

OBSTETRICS

TABLE I—MATERNAL MORTALITY

Deaths	Patients	Mortality rate per 10,000
Hospital and outside deliveries	Obst admissions	14
Hospital deliveries	Hospital deliveries	15
Hospital deliveries	Hospital live births	16
All except abortions, ectopic pregnancies and chorion-epithelioma	All admissions except abortions, ectopic pregnancies, and chorionepithelioma	17
All except abortions, ectopic pregnancies and chorion-epithelioma	All deliveries	19
All except abortions (Margaret Hague Hospital)	Live births	22
All deaths (New York Lying-In Hospital)	All admissions	29
All deaths (Chicago Lying-In Hospital)	All patients	32
International list of causes of death	Live births	32
All deaths	Live births	38

About 15 minutes are allowed for the infusion of citrated blood, and 50 c c are infused before bleeding is started. This is accomplished by exposing the radial artery at the wrist and cutting a flap from its wall. Blood is collected in 1 oz medicine glasses which are emptied into a graduated bottle.

The infusion is always kept about 50 c c. ahead of the bleeding. From 50 to 75 c c more blood is infused than is withdrawn.

A 10 c c syringe of 10 per cent calcium gluconate is kept on hand at all times, and if signs and symptoms of hypocalcemia develop, 5 c c are given slowly, usually, for transfusions of 500 c c of blood or less, this is not needed unless the procedure is carried out too fast. Penicillin was given to prevent infection.

The cases are reviewed in detail. Of the 28 cases, 16 were very severe, 6 were moderately severe, and 6 were mild. Only 7 infants succumbed. The authors favor fresh blood as compared to bank blood.

It is believed that the most reliable index of severity of the disease is provided by antibody titrations of the maternal univalent Rh antibodies as well as by tests for the presence of univalent antibodies in the infant's blood.

BYFORD F. HESKETT, M D

MISCELLANEOUS

Maternal Mortality: An Analysis of the 10 Year Period from 1937 Through 1946 at the Cincinnati General Hospital R D BRYANT and N S AS
SALV *West J Surg*, 1948, 56 611

The authors point out that there is no standard definition of maternal mortality, nor is there any standard method of reporting maternal mortality as rates. They have defined maternal mortality as (1) deaths during pregnancy and labor from any cause whatsoever, (2) deaths during the puerperium (the puerperium is considered as the 6 weeks following the day of delivery) from any cause whatsoever, (3) deaths any time after delivery due directly to complications or sequela of pregnancy or delivery, and continuously present since then, (4) deaths due to chorionepithelioma of uterine origin. As is well known, the bureau of census figures are based on the

number of maternal deaths in relation to total live births. In reporting mortality rates, other clinics use a variety of different methods for determination of the rate.

The latest statistics reveal a significantly higher maternal mortality among negroes, and that nearly all of the deaths occurred among patients, white or colored, who had had poor or no prenatal care. The article is accompanied by an interesting table showing the difference in mortality rate per 10,000 cases, and calculated in a variety of different ways that have been reported in the past literature.

This table clearly reflects the fact that many current reports are not comparable and that there is a striking need for some standard method of reporting maternal mortality. In regard to the preventability of maternal deaths, the authors are of the belief that whereas one could discuss the overall preventability of any group of complications, such standards applied to a single patient are not sufficiently reliable to be significant.

JAMES F. DONNELLY, M D

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Device for Obstructing the Urinary Flow in Intravenous Urography (Urografia a deflusso ostacolato) G ZACCONE and L CONZI *Radiol med*, Milano, 1948, 34 548

The authors propose the use of a small distensible balloon attached to a common catheter and a simple manometer which, when introduced into the bladder and inflated, serves to obstruct the flow of urine into the bladder. They suggest that the first films be made 3 or 4 minutes after the cessation of injection, and that the balloon then be inflated to a pressure between 40 and 50 mm of mercury. The air required is found to vary from 400 to 800 c.c. The procedure is better tolerated by the patients than the usual external compression, and it results in a more detailed and dependable visualization.

EDITH B FARNSWORTH, M D

Double Formations of the Pelves of the Kidneys and the Ureters. Embryology, Occurrence, and Clinical Significance BENGT NORDMARK *Acta radiol*, Stockh., 1948, 30 267

The author examined 4,774 urograms taken in the 5-year period from 1942 through 1946. In this group he found 201 cases of double kidney pelvis, a percentage of 4.2. In 138 of these cases there was also a double formation of the ureter, a percentage of 2.8.

Of the 201 cases of double formation of the kidney pelvis, 46 were bilateral and 155 unilateral. Of the 138 cases of double formation of the ureter, 19 were bilateral and 119 unilateral.

When the different kinds of double formations of the ureter were arranged in order according to their occurrence, the following figures were obtained:

1. Cases with unilateral incomplete division of the ureter, 60 (1.3 per cent)
2. Cases with unilateral complete division of the ureter, 59 (1.3 per cent)
3. Cases with bilateral complete division of the ureter, 11 (0.2 per cent)
4. Cases with bilateral incomplete division of the ureter, 5 (0.1 per cent)
5. Cases with complete division of the ureter on one side and incomplete division on the other, 3 (0.06 per cent)

Of the 201 patients with double formation of the pelvis, 98 were women and 103 men. Of the 155 unilateral cases of double formation of the kidney pelvis, 62 were on the right and 93 on the left side. There was no evidence of any family connection in these cases of malformation.

The author reports the statistics of other investigators and outlines the embryologic theories causing reduplications. Most of the writers believe that these malformations are of clinical significance.

Of the 201 case analyses, 48 showed symptoms of cystitis or pyelitis and, further, 15 showed a renal calculus with a calculus in the ureter in conjunction with double formation of the kidney pelvis or of the ureter. However, also 13 cases of calculus of the kidney or of the ureter on the side on which the kidney was not affected by any malformation were found. The author suggests that the reason so many cases show symptoms of disease, lies in the type of material.

Most of the patients on whom such a thorough and costly examination as a urogram is carried out, show symptoms in the urinary passages. This also means that these malformations are not quite so common as an investigation of this kind seems to indicate. The author believes that from the viewpoint of therapy, it is very important to know whether or not a double kidney is present, and he presents 5 cases in which this knowledge was of paramount importance.

ROBERT O BEADLES, M D

A Case of Chyluria of the Right Kidney (Un caso de quiluria de riñón derecho) JAVIER HÓDER *Arch españ urol*, 1948, 5 99

A typical case of chyluria is here reported, although operation had not yet been done, in order to present its odd history and the characteristic roentgen picture of this rare condition. About 10 years ago the patient, a 43 year old single woman who had never been outside of Spain, except one time when she went to Bordeaux in France, was laparotomized through a supraumbilical, midline incision for an acute condition of the abdomen. A year later her appendix was removed through a right lower abdominal incision. Six years later the patient suffered from headaches and noted that the urine looked dirty. The milky, grayish color was shown to be due to the presence of chyle. This chylous discharge showed a close relationship to the recumbent body posture. The urine was practically clear during the day but developed the opalescence during the night—usually after midnight.

Cystoscopy disclosed the milky, chylous fluid coming from the right ureter, and ascending pyelography disclosed the characteristic lymphatic reflux.

The author surmises that the condition has something to do with the cicatricial developments following one or the other of the abdominal operations. Probably the supraumbilical incision marked the origin of the condition interfering with the lateral flow and directing it against the hilus portion of the kidney.

A further report on this case will be made when the patient makes up her mind to be operated upon, which decision the author surmises will not be too far distant in the future.

JOHN W BRENAN, M D

Pararenal Sympathicoblastoma in Children Under 5 Years of Age (*Sympatcblastomi pararenali in bambini sotto i cinque anni*) **GIORGIO DE MAIO**
Urologia, 1948, 15 393

Four cases of pararenal sympathicoblastoma in children under 5 years of age are reported by the author. In 3 cases the preoperative diagnosis was pararenal tumor and in 1 case that of kidney tumor was made. The patients' ages ranged from 15 months to 4½ years.

The tumors were malignant, had a dysontogenetic etiology and showed a neuroblastic evolution. In the histologic examination it was possible to distinguish three varieties: sympathogoniomas, neuroblastomas, and ganglioneuromas.

The tumors occur more frequently in the female than in the male sex. All 4 patients in the cases reported by the author were girls.

The tumors vary in size, have either a smooth or a nodular surface and a fibrous capsule, and may be adherent to the spine and the paravertebral tissues.

Pain in the affected hypochondrium or the flank is followed sooner or later by pallor, other signs of cachexia, and visceral or osseous metastases.

The discovery of a tumor on palpation, and also ascending and descending pyelography help to establish the diagnosis. Malignant lymphogranulomas, tumors of the liver, and splenomegaly should be considered in the differential diagnosis. A tumor of the suprarenal gland cannot be excluded with certainty before the operation.

The prognosis is poor and seems to have no relation to the degree of maturity of the tumor.

Either the transperitoneal or the lumbar route is used for exploration and for removal of the tumor if possible.

Postoperative irradiation may prolong life.

JOSEPH K. NARAT, M.D.

Results of Surgical Treatment of Unilateral Nephropathy in Hypertension (*Résultats du traitement chirurgical des néphropathies unilatérales dans l'hypertension*) **J. CIBERT, M. REVOL, and S. KANTOR**
J. urol. méd., Par., 1948, 54 538

The authors discuss the cases of a series of 20 hypertensive patients in whom surgery of the kidney was performed for various lesions. Eighteen of the patients underwent nephrectomy, 1 decapsulation, and 1 pyelotomy for a kidney stone. The renal pathology included hydronephrosis, tuberculosis, lithiasis, nephrosclerosis, and hypoplasia of the kidney.

Sixteen of the patients showed a definite, some of them a spectacular, decrease of the hypertension. Even in those in whom the blood pressure decreased only a little or not at all, the other symptoms such as headache, asthenia, and visual disturbances cleared up more or less.

It is important to select judiciously those patients who are likely to benefit from the operation. Strictly unilateral severe nephropathies are comparatively rare. Only persons under 50 years of age with hyper-

tension of relatively recent origin can be expected to show amelioration or, in rare instances, complete cure.

The Remaining Kidney in Tuberculous Cystitis after Nephrectomy (*Le rein restant dans la cystite tuberculeuse après néphrectomie*) **GEORGES MAYOR**
J. urol. méd., Par., 1948, 54 513

The author studied a series of 164 cases of tuberculous cystitis after nephrectomy and its influence on the remaining kidney. The cases were collected partly from the literature and partly from the hospitals at Paris and Lyon, France, and at Bern and Zurich, Switzerland.

The relations between renal and vesical tuberculosis are little known at present. It has been proved experimentally that the introduction of Koch bacilli into the bladder has never produced tuberculous cystitis. Hence, it can be concluded that infection does not occur from contaminated urine. In most cases, infection of the bladder takes place by way of the lymphatics along the ureter from the tuberculous kidney. The initial lesions are always situated at the ureteral orifice. Hematogenous infection occurs in rare cases only, if at all.

After nephrectomy the cystitis may clear up completely, or reinfection may occur, either from the remaining kidney, a focus in the prostate, or from the stump of the amputated ureter. Recurrences of an apparently healed tuberculous cystitis may also be caused by an intercurrent nonspecific infection of the bladder.

Retrograde infection of the remaining kidney can occur only when the intramural portion of the ureter becomes involved. The ureter runs obliquely through the bladder wall to the base of the trigonum. As a result, in normal cases the internal os is closed in increased vesical pressure like a valve, and no reflux can take place. Intramural tuberculous ureteritis, however, leads to diminution of the tonus, sclerosis, and insufficiency, or, in rarer cases, to stenosis of the intramural ureter. Clinical symptoms of insufficiency are pollakiuria, pyuria, and pains in the lumbar region of the remaining kidney, especially when the bladder is full and during micturition. Cystoscopy reveals a wide open orifice of pale color, diminished tonus, and poor peristalsis. Often specific lesions or scars can be seen on cystoscopic examination. The amount and intensity of reflux can be verified by cystography or intravenous urography. The insufficiency of the orifice combined with the diminished tonus leads to gradual dilatation of the ureter, which may reach enormous dimensions. The pathological reflux is aggravated by spasms of the vesical sphincter and difficulties of urination. In men, tuberculous prostatitis and urethritis are additional factors which maintain the cystitis, ureteritis, and retrograde infection of the remaining kidney.

Various pathologic conditions of the remaining kidney may result. Hydronephrosis and gradual destruction of the renal parenchyma are due to the reflux and increased intraureteral pressure. Whether

tuberculosis of the remaining kidney is hematogenous or due to the reflux from a tuberculous bladder is still an open question. Unjudicious ureteral catheterism may also play a causative role. Since all tuberculous bladders are secondarily infected, ascendant pyelonephritis and purulent nephritis are frequent complications. Other complications include prostatitis, epididymitis, lithiasis of the kidney or bladder, and incontinence.

Medical treatment has only a temporary effect, if any. Vesical instillations give relief for some time but do not influence the specific lesions. Streptomycin had been applied only in 1 case, without success. Surgical treatment in the area of the ureter includes meatotomy, dilatation of the stenosed ureter (3 cases), permanent ureteral catheterism (3 cases), and ureterotomy followed by retrograde catheterism (2 cases with poor result). Surgery of the bladder includes simple cystostomy (8 cases), plastic operations (which are rejected by the author as too dangerous), and ureterocystoneostomy, which was done in 1 case with excellent success. Resection of the neck of the bladder, either for stenosis or spasm, was done in 17 patients. Ten of these had good results, 4 fair results, and 3 poor results.

Implantation of the ureter in the colon was done in 18 cases for various indications. Most of the patients died of ascendant pyelonephritis and uremia within 2 years. External ureterostomy is much safer than this dangerous operation. Elimination of the bladder gives prompt relief of the pains, cures the cystitis, and abolishes the danger of reflux with all its sequelae. The late results in 99 patients were good in 69, fair in 7, and poor in 23.

Nephrostomy is done in pyonephrosis only, as a rule. In 7 of 13 patients, the results were good. In 4 additional patients nephrostomy was followed by implantation of the ureter in the sigmoid with good results.

Cause of Hematuria HAMILTON W. MCKAY, H. HAYNES BAIRD, and KENNETH M. LYNCH, JR. *J Urol*, Balt., 1949, 61: 1.

The authors report in detail 2 cases of vascular lesions of the renal papillae, and present their conclusions, based on experience in these 2 cases, and a review of the literature.

The first case was that of a 39 year old negro who, in 1944, had gross hematuria which persisted for several days and for which he received no therapy. Three months prior to admission to the hospital, on February 18, 1947, the hematuria recurred. After it had been determined that he was bleeding from the left kidney, the left renal pelvis was irrigated with 1 per cent silver nitrate without beneficial results. Complete urological and hematological studies failed to reveal the etiology of the hematuria. After an interval of 3 months, and a 10 to 15 pound weight loss, he was hospitalized. Except for grossly bloody urine, no abnormalities were found on a complete survey. A nephrectomy was performed. The pathologist reported that the kidney was normal ex-

cept for the tip of one pyramid in which there was a collection of dilated veins with hemorrhage into the surrounding tissue. Microscopically, rupture of a dilated vein into the pelvis of the kidney was noted.

The second case was that of a 67 year old white housewife who, on retrograde pyelography, presented a picture similar to that in Case 1, with gross hematuria and right hydronephrosis, and moderate left hydronephrosis. Because of the persistent hematuria and bizarre left renal shadow, a nephrectomy was performed. The pathological report read in part: "At the lower pole is encountered a pyramid, the apex of which contains numerous small foci of hemorrhage and from which a small amount of sanguineous fluid can be expressed. The mucosa of the adjacent calyx is somewhat hemorrhagic and appears to be ulcerated. Histological sections through these areas show an extensive inflammatory infiltration in the medullary and peripelvic portion. In one area the histologic findings are suggestive of a direct continuity between a moderate sized vein and a markedly inflamed portion of the calyx with extensive necrosis of the peripelvic tissue and massive hemorrhage. Focal, partially necrotizing pyelonephritis in isolated calyces with massive hemorrhage."

In their review of the literature, the authors found 21 cases in which similar lesions were classified as varicosities, and 92 other cases which were classified as angioma of the kidney, chronic papillitis, chronic hemorrhagic papillitis, or chronic inflammatory and vascular changes in the papillae. Of the 92 cases, only 15 were believed to have contributed to the literature on the subject. The cases were classified in two groups, one group including the cases of vascular irregularities—either renal varix or angioma—the other, those which showed lesions interpreted as inflammatory in nature.

The authors propose that the lesion in their first case be called a hamartoma—"the congenital overdevelopment of some tissue element which belongs at the site at which it is found." The second group of cases have been combined under a diagnosis of hemorrhagic papillitis. Isolation of a bacterial agent was unsuccessful. However, in many of the cases reported by others the condition was apparently pyelitis due to the colon bacillus with ulceration into a sizable vessel.

In cases in which the bleeding is persistent, serious and unilateral nephrectomy is recommended after conservative attempts have failed.

BLADDER, URETHRA, AND PENIS

Occlusion of Vesical Orifice after Suprapubic Prostatectomy ALBERT E. GOLDSTEIN and SEYMOUR W. RUBIN. *J Urol*, Balt., 1948, 60: 499.

Complete occlusion of the vesical orifice following suprapubic prostatectomy is a very rare complication. Only 26 cases have been recorded in the English and American literature, including the 3 cases reported by the authors.

All of the reported cases have the occluding diaphragm of mucosa at the vesicoprostatic juncture. When the suprapubic sinus persists, occlusion below should be suspected. Persistent instrumentation in the presence of such an occlusion at the vesical orifice may result in serious complications.

The treatment of occlusion at the vesical orifice consists of suprapubic cystotomy and excision of the diaphragmatic obstruction over a urethral sound. The prognosis is excellent. Complete occlusion following operation may be prevented by careful excision of mucosal tags and ledges and by the use of an indwelling catheter.

FREDERICK A. LLOYD, M.D.

Cystitis Glandularis HANS R. SAUER and MICHAEL S. BLICK *J. Urol.*, Balt., 1948, 60: 446

Cystitis glandularis is of fairly uncommon occurrence and the difficulties encountered in the diagnosis of this lesion have been adequately described by various authors. Because of its often confusing cystoscopic and microscopic appearance, the condition may easily be mistaken for carcinoma, and prolonged observation is necessary in some cases before the true nature of the lesion can be recognized.

Following a study of 7 cases, the authors have come to the conclusion that cystitis glandularis should be considered a separate clinical entity. Its recognition may be difficult in some instances, yet there are certain findings which seem to be pathognomonic.

Cystitis glandularis need not impair the patient's well-being to any great extent. Although cystoscopy revealed quite extensive lesions, and although the patients were suffering from a chronic condition with symptoms of varying severity and duration, it was noted that their general health remained unimpaired by the disease. As a rule the symptoms of the disease were not characteristic. Dysuria, always in combination with frequency, was the most common complaint. Intermittent hematuria was the next frequent symptom, and in 1 patient the persistent elimination of clear and tenacious mucus was the only complaint. Since hematuria, frequency, and dysuria are known to occur as a result of various urological disorders, not too much diagnostic significance can be attributed to their occurrence. It appears likely that they are caused by superimposed infection rather than by the disease itself. In contrast, constant elimination of clear mucus during and/or after urination is of diagnostic importance because it indicates the presence of mucus-producing glands in the genitourinary tract. However, since mucin may be secreted in such small quantities that its elimination may occur unnoticed by the patient, it is advisable to carry out mucin tests whenever glandular cystitis is suspected.

The vesical neck and trigone, as well as the lower posterior and lower lateral walls, are the site of predilection, yet other parts of the bladder may occasionally be affected by the disease. It was noted that the lesions remained localized to the areas

where they were originally observed, and neither progression nor regression took place throughout the period of observation.

It is generally agreed that cystitis glandularis remains more or less confined to the bladder proper. The absence of changes in the prostate and seminal vesicles, as determined on rectal examination, was also conspicuous.

Cystoscopic examination represents the most valuable procedure in the diagnosis of glandular cystitis. In the cases observed the bladder capacity was not significantly reduced and the instrumentation was not unduly painful, although some of the lesions had assumed considerable proportions.

The cystoscopic picture of cystitis glandularis appears to be characterized by two distinctive types of lesions. The first consists of mammillated bleblike structures which are separated by deep ridges. Although the lesion resembles bullous edema at first sight, it differs because the bleblike elevations are fleshy in appearance and lack transparency.

The second type is characterized by the formation of fleshy villouslike proliferations. While the first type may give the impression of tumor growth underneath the mucosa, the second may very easily be mistaken for tumor originating in the mucosa itself. However, it is characteristic for both forms that the transition from diseased to apparently unaffected bladder mucosa is usually quite abrupt.

Although the afore-mentioned factors are of considerable diagnostic value, the final confirmation of the diagnosis rests on the histologic findings. The microscopic appearance of this condition may closely resemble either squamous cell carcinoma or adenocarcinoma.

The treatment of cystitis glandularis should be conservative. Active bleeding from a small area can be arrested by electrocoagulation. If infection is present, its source, if determined, should be eliminated. In other cases, it should be treated with urinary antiseptics.

FREDERICK A. LLOYD, M.D.

Gangrene of the Penis (Gangrenas del pene) JORGE LOCKHART *An. Fac. med. Montev.*, 1948, p. 957

The male urethra forms three angles: (1) the inferior angle, created by the intracavernous diaphragm, (2) the middle or cavernous angle, at the site of separation of the corpora cavernosa where they lose their connection with the pubic bone, and (3) the superior angle, where the pendulous portion begins.

Periurethritis at the level of the third angle has the greatest tendency to produce gangrene of the penis. In a lesser degree, the second angle shows a similar tendency.

Gangrene of the penis shows a multiplicity of clinical forms, the most frequent one being the spontaneous or fulminating form described by Fournier.

The gangrene may be superficial or deep, and it may take an acute or chronic course. Gangrene is always preceded by a pregangrenous lesion such as an erosion or balanoposthitis.

There is a definite histopathologic, etiologic, and evolutionary parallelism between the cutaneous gangrene and certain forms of phagedenic conditions.

Phimosis creates optimal conditions for the development of a gangrene by favoring inflammatory processes within the balanopreputial cavity.

Infection is the most important factor in the etiology of the gangrene of the penis, but chemical factors, such as the local application of kerosene, have also been mentioned in the literature.

Postoperative progressive cutaneous gangrene, similar to conditions of the abdominal wall described by Meleney, has been observed by the author.

In 2 instances the author saw a dissecting pericavernitis of gangrenous type.

The glans penis is the most frequent site of gangrene which rapidly invades deeper tissues. In the anatomic sense the glans is quite independent from the rest of the organ, a fact which allows the performance of its amputation.

An inflammatory phimosis, responsible for a grave general condition, is strongly suggestive of gangrene of the penis and demands an immediate dorsal split or circumcision.

Gangrene of the penis, whatever clinical form it assumes, has a great tendency to limit itself spontaneously, and already in early stages forms a line of demarcation. Therefore, although the results are mutilating, the prognosis for life is good.

As to the treatment, exposure to air, associated with the local and general administration of anti-infectious remedies, is sufficient to lead the evolution of the process toward a cure. If the lesion is extensive, its borders should be excised with electrosurgery.

JOSEPH K. NARAT, M.D.

GENITAL ORGANS

Carcinoma Cells in Prostatic Secretions DONALD D. ALBERS, JOHN R. McDONALD, and GERSHOM J. THOMPSON *J. Am. Med. Ass.*, 1949, 139: 299.

This study was conducted to demonstrate that carcinoma of the prostate can be diagnosed by examination of the prostatic secretions. Other information sought for concerned the accuracy of this test in regard to prostatic carcinoma in general and well differentiated prostatic carcinoma in particular, the criteria for the diagnosis based on a study of the prostatic secretions, the diagnosis of prostatic malignancy before it is clinically evident, and the components of prostatic secretions which might be confused with malignant cells.

Prostatic secretions were obtained by the customary method of prostatic massage, and a drop of secretion was placed near the end of each slide. This was spread in a circular manner with an applicator. Before drying, the slides were immersed in an alcohol-ether mixture (equal parts of 95 per cent alcohol and ether) in Coplin jars. An attempt was made to prepare at least four slides for each patient. These slides were left in the fixative for not less than 30 minutes.

The slides were passed through three strengths of alcohol (80, 70, and 50 per cent) and then through tap water. They were then either allowed to dry or started on the rest of the staining procedure immediately. The technique used was a routine hematoxylin-eosin method with certain shortcuts, but any routine hematoxylin-eosin technique should be satisfactory after some experience has been obtained.

All slides from each patient were examined at 100 power, the mechanical stage being used to assure complete coverage. Any suspicious cell was examined under 430 power for identification and, when considered worthy, was marked with ink for further reference. In general, it took from 20 to 30 minutes to cover four slides adequately, particularly if no malignant cells were seen. When malignant cells were present, they were usually found on the first slide and sometimes the diagnosis could be made in a few seconds.

Initially, in order that an acquaintance with the prostatic epithelial cells in secretions of both benign and malignant prostates might be obtained, smears were made by expressing, on slides, pieces of prostatic tissue removed at transurethral resection and studied. In all, about 30 slides were studied, the findings revealed benign conditions and the four grades of cancer of the prostate (Broders' classification). Then the prostatic secretions from two series of cases were studied. Series 1 consisted of 100 patients with clinically benign prostatic hypertrophy, all scheduled for transurethral resection, and series 2 comprised 41 patients with clinically malignant disease of the prostate, most of whom had obstructive symptoms and were scheduled for operation. Only one specimen was taken in each case.

The benign secretions contained few cells except when prostatitis was present.

Malignant secretions contained benign cellular components in variable amounts, but usually the amount of prostatic epithelium was increased. In this study, every secretion called "positive" for carcinoma cells contained clusters of malignant cells. In poorly differentiated carcinomas, single carcinoma cells were also plentiful. In the well differentiated carcinomas, the cells were not very typical and the presence of clusters of cells were considered essential for the diagnosis.

Confusing components of prostatic secretion were many, and the time spent in distinguishing them from malignant cells varied. The nuclei of squamous and transitional epithelial cells are large, and when the cytoplasm stains poorly these cells appear to have large nuclei and to lack cytoplasm. The nuclei may even contain pale nucleoli, but usually the similarity of these nuclei to those of other typically squamous cells and the lack of hyperchromicity were revealing.

A very confusing cell-like structure was found when spermatozoa were seen in the smears. These structures appeared to consist of homogeneous dark blue nuclei with very eosinophile cytoplasm. Even nucleoli were apparent at times. These cell-like

GENITOURINARY SURGERY

structures were easily recognized most of the time, but their recognition was considerably difficult until experience was gained.

In the secretions of 3 of the 100 patients in whom a diagnosis of benign hypertrophy was made preoperatively, carcinoma cells were seen. The observations in these 3 cases were confirmed pathologically at transurethral resection. Similar histologic pictures were presented on examination of sections of tissue, the degree of malignancy being graded (Broders' method). In these 3 cases, the symptoms, which were similar and referable to the urinary tract, included frequency, nocturia, urgency, smallness of the stream, difficulty in starting the stream, and some burning. The ages of these 3 patients were between 40 and 60 years.

In the fourth case in this series the prostate was found to be malignant (grade 1) on histologic examination. There were small glands that lacked papillary infolding, there was lack of stroma, and it was difficult to distinguish the cells from normal cells. However, the secretion from this patient was not considered diagnostic when it was compared with the secretion from benign prostates that showed, on section of tissue at surgical removal, hyperplasia of the epithelium and resultant filling of some of the acini.

The cases in this series in which secretions were not obtained or in which no proof of malignancy was obtained on examination of the prostatic tissue were all cases of advanced carcinoma of the prostate clinically. Many of the patients had metastases, and 5 of these from whom secretions were not obtained had undergone resection previously.

The patient whose prostatic secretions failed to reveal carcinoma was observed, on examination of prostatic tissue, to have carcinoma of the most highly differentiated grade (grade 1).

In the 1 case in which prostatic secretions were positive for carcinoma, every piece of 19 gm of tissue removed at transurethral resection was sectioned and examined but carcinoma was not found.

In 2 of the cases in which both the secretion and tissue were positive for carcinoma, the lesions were well differentiated carcinomas showing gland formation but malignant changes in the cells (grade 2), and in the rest the lesions were poorly differentiated carcinomas (grades 3 and 4). In 4 cases there was some question preoperatively as to whether the patients had a malignant lesion.

Bladder Neck Obstruction. A Review of 508 Cases Treated by Endoscopic Resection. HENRY MOR-
TENSEN. *Med J Australia*, 1948, 2: 714.

The author briefly reviews the development of the periurethral route in operations for bladder neck obstruction. The first definite description of such an approach was given in the sixteenth century by Ambroise Paré. In recent years, with the advent of the electric current and the galvanocautery, instruments were devised to remove tissue by coagulation

The varied instruments of this period are described and illustrated. The procedures were blind, and the scarring, sepsis, and hemorrhage doomed the method to failure. Then the development of the cutting current and fiberoptic endoscopic vision ushered in an era of enthusiasm for periurethral prostatic resection. After an early optimistic period, a reaction set in and the complications such as perforation, stricture, hemorrhage, incontinence, and inadequate resection were stressed as limitations of the operation. The position today has righted itself and endoscopic resection has found its proper place.

Over a 5-year period 689 cases of bladder neck obstruction were observed by the author in his private practice. In 508, or 82 per cent, he performed endoscopic resection with the McCarthy electro-tome. He presents his experiences, in which the results were considered very good. The average age of the patients in this series was 67.5 years. The mortality rate was 3.1, a figure which would have been lower had the author not accepted comparatively poor risks for this procedure. Patients were up from the first to the fourth day and usually out of the hospital on the tenth day. Postoperative complications were relatively infrequent. Some early urinary sepsis and residual urine in the immediate postoperative period cleared with epithelization of the resected area and recovery of the bladder tone.

The author is particularly fortunate in that readmission for secondary hemorrhage occurred less than once a year. An inflatable bag with continuous 48-hour irrigation and no traction was used. Some degree of incontinence was present in 23 cases, but in only 2 of them was there any degree of permanence. This complication is now commonly thought to be due to inadequate resection which permits the prolapse of tissue through the external sphincter.

Formation of stricture is obviated by properly executed meatotomy or perineal urethrotomy through which the resectoscope is introduced if there is difficulty in introducing a large sound. There were 10 stricture complications, in 1 case dilatations were necessary for 6 months. Persisting obstructive symptoms requiring further resection occurred in only 6 cases.

There is no indication as to how much tissue is removed, but one obtains the impression that resection down to the capsule is not done. A massive obstructing gland is considered a contraindication to endoscopic approach. Questionnaire follow-up on subjective relief elicited graded responses varying from excellent in 72 per cent of the patients to poor in 1 per cent.

ALLAN K. SWEETIE, M.D.

Perineal Prostatectomy Today. DANIEL R. HIGBEE. *J Am Med Ass*, 1949, 139: 141.

The purpose that Dr. Higbee had in presenting this subject was twofold: first, to present additional evidence on perineal prostatectomy as to its relative safety and good end results and, secondly, to endeavor to stimulate wider interest in the perineal surgical treatment of cancer of the prostate.

Perineal prostatectomy has not had the popularity of suprapubic and retropubic prostatectomy or transurethral resection. The author's reasons for this are (1) lack of familiarity with anatomy of the male perineum, (2) inadequate teaching or complete lack of it in many of the well organized medical centers, and (3) the lack of courage of the surgeon to follow through and master the approach in spite of having previously encountered a difficult case, or one of the more serious complications associated with this surgical procedure.

Perineal prostatectomy is the one operation by which almost any pathological change encountered in the gland can be adequately dealt with. The great advantage of this operation, according to Hugh Young, is that it is performed in complete visual control of the operator, hemorrhage that is encountered is stopped, the enucleation is complete, the verumontanum, ejaculatory ducts, the internal and external sphincters are protected, dependent drainage for urinary and inflammatory secretions is obtained, and the lowest mortality rate is secured.

The disadvantages of the operation are well known. The patient's position during operation is unpleasant and may be associated with respiratory or cardiac embarrassment.

The author's series of 350 consecutive cases consisted of 334 simple enucleations, 2 subtotal prostatectomies, and 14 radical perineal operations. The 14 radical operations were separately considered.

In the group of 336 perineal prostatectomies for benign hypertrophy of the prostate, the mortality was 18%. Complications developed in 39 patients, or 11 per cent of the cases.

Postoperative hemorrhage required that 13 patients be returned to the operating room for removal of clots on the day of operation, however, in 3 cases hemorrhage occurred on the sixth postoperative day.

Rectal injuries occurred in 11 cases and fistulas occurred in 4, or 12 per cent of the cases. In 7 of the 11 cases perineal operation was abandoned, suprapubic enucleation was substituted in 2, and transurethral resection was done in 5 cases.

Pulmonary complications were present in 13 cases. In 7 of these the diagnosis was embolic pneumonia, in 4 bronchopneumonia, in 1 lobar pneumonia, and in 1 diaphragmatic pleurisy.

Cardiac complications were minimal, with 2 deaths. Coronary symptoms developed in 3 patients, and in 1 patient an acute decompensation with pulmonary edema followed the operation.

The author concluded that cardiac patients withstood perineal surgery well, although there is probably less immediate risk if the patient is operated upon by transurethral prostatic resection.

A persistent perineal fistula developed in one case.

The fear of urinary incontinence is more widespread than is justified. The methods of avoiding this complication consist of (1) strict observance of the lines of cleavage, especially separating the apical attachment of the rectourethralis muscle, (2) avoid-

ance of unnecessary dissection and exposure, there by interrupting as few nerve fibers as possible, and (3) gentleness and care in retraction both laterally and anteriorly in the region of the perineal body and the external sphincter.

The author concluded that perineal prostatectomy can be carried out with a low mortality, little blood loss, few complications, and good end results at any age.

Total prostatectomy is not a particularly difficult procedure if one is frequently performing other perineal operations, and surgical removal of the prostate remains today the only means of producing a cure in prostatic carcinoma.

Of the 14 patients who were subjected to radical perineal prostatectomy, 2 did not have evidence of cancer on pathological examination. In the 12 patients with proved cancer of the prostate, 4 were castrated in conjunction with radical perineal prostatectomy. The author's statistical end results seemed to indicate the value of this operation for carcinoma of the prostate. Previous to this type of operation, his patients were prepared by catheter drainage, and 5 mgm of diethylstilbestrol were administered daily from 10 to 14 days prior to operation, thus the operability was considered to be facilitated by preliminary treatment with diethylstilbestrol.

The author concluded that radical perineal excision should be attempted in all cases of cancer confined to the prostate gland and in those borderline cases which respond to diethylstilbestrol therapy.

CONRAD A. KUEHN, M.D.

Retropubic Prostatectomy THOMAS D. MOORE, J. Urol., Balt., 1949, 61: 46

Forty-six retropubic prostatectomies are reported and reviewed. The author adopted this procedure because of its apparent advantages, namely, greater degree of comfort, less evidence of shock, omission of suprapubic vesical drainage, and a smoother and shorter convalescence. Compared to transurethral resection, large glands are removed retropubically in less time, the operation is concluded at one sitting, less bleeding occurs postoperatively, the period of convalescence is the same, the risk is no greater, there is less immediate postoperative discomfort, and the functional results are good. During the 7 months in which the 46 retropubic prostatectomies were performed, the author performed 2 primary suprapubic prostatectomies and 193 transurethral prostatic resections.

Examination of the patients consisted of a general physical survey, routine 2 glass urinalysis, test for residual urine, pneumocystogram with the patient in the semilateral position, estimation of nonprotein nitrogen, phenolsulfonphthalein test in the usual manner, and, when advisable, an intravenous urogram. The digital examination and the pneumocystogram afford a reliable method for determining prostatic size. Cystoscopy is not routinely employed. The judicious use of sulfonamides prophylactically is suggested. If residual urine is greater than 60 cc,

an indwelling Foley catheter, size No 16 F, is inserted. If the cardiovascular status permits, the patient enjoys a large fluid intake and a regular diet. At the optimum time, dependent upon the results of the examination, the operative procedure is scheduled. Vas ligation is performed at the time of prostatic surgery.

The special Millan instrument facilitates the procedure. A suprapubic transverse incision is made about 2 cm above the symphysis, incising the recti sheath. The muscles are separated. The Trendelenburg position is attained and the dissection is carried down to the anterior aspect of the prostate gland, which is cleaned by gauze dissection.

Electrocoagulation secures the adjacent vessels. The prostate is mobilized anteriorly and laterally with sponge sticks. The prostatic capsule is incised transversely with the needle electrode and cutting current. The capsule is separated laterally and anteriorly with curved forceps in the cleavage plane. The margins of the capsule are grasped with special T capsule forceps. With finger dissection, the enucleation is completed after the urethra has been cut near the apex. The vesical neck attachments are clamped, cut, and fulgurated. If the vesical neck requires resection, a V-shaped wedge is removed inferiorly. After finger inspection of the bladder, a No 24 F Foley catheter is passed into the urethra, at which time a strip of oxidized gauze and a suspension of colloidal sulfathiazole is placed around the bag of the catheter. The latter is inflated so that it remains in the prostatic fossa with the tip of the catheter jutting into the bladder. The prostatic capsule is closed with 2 layers of chromic catgut interlocking sutures. The wound is closed in the conventional manner.

A detailed comparison is made between the suprapubic, retropubic, and transurethral prostatectomy. A table of comparative postoperative data of 46 cases in each series revealed that the catheter was removed in an average of 12 days in the suprapubic group, and in half that time when either of the other 2 procedures were performed. The average postoperative hospitalization was 15 days in the suprapubic group, or 4 days more than the average of the other 2 groups. The early functional result was somewhat better with the suprapubic and retropubic group than with the transurethral group.

While osteitis pubis might be confused with obturator neuritis and chondritis, the distressing symptom of this complication occurred in 8 (17%) of the 46 retropubic prostatectomies. This complication did not occur in the suprapubic or transurethral group. There was 1 death in the suprapubic group, 2 in the transurethral group, and none in the retropubic group.

An evaluation is made of late functional results following retropubic prostatectomy. Preoperative and postoperative cystourethrograms illustrate the results.

The author suggests that once osteitis pubis is prevented, the retropubic prostatectomy will replace

much of the suprapubic prostatic surgery for hypertrophies of unusually large degree.

PETER L. SCARDINO, M D

Sixty-Five Prostatectomies According To Freyer's Method (Sessantacinque prostatectomie secondo Freyer) MARIO FERNANDEZ *Urologia*, 1948, 15 407

Although the enthusiasm for electroresection of the prostatic gland is growing, the author still favors the suprapubic prostatectomy because its technique is easy, the functional results are better than those following the perineal resection, the operation offers the opportunity for the beneficial drainage, and the postoperative mortality is low.

Of 65 patients who underwent the suprapubic prostatectomy, 3 died, 1 from bronchopneumonia, 1 from septicemia, and 1 from a cardiorenal disease. Twelve patients were between 50 and 60 years of age, 36 were in the sixties, and 17 were in the eighth decade of life. The time interval between the two stages of the operation ranged from 15 to 70 days. The nitrogen contents of the blood, d'Ambard's coefficient, the blood pressure, and the general condition of the patient were the determining factors in the selection of the interval between the stages of the operation.

The author has abolished the use of sponges for hemostatic purposes except in cases of severe hemorrhage which peril the patient's life.

JOSEPH K. NARAT, M D

Varicocele, Technique of Operation of Eurico Branco Ribeiro (Varicocele, técnica de la operación de Eurico Branco Ribeiro) JOSÉ YOEL *Día méd*, B Air, 1949, 21 156

For the past 2 years the author has obtained very satisfactory results from the operation of Branco Ribeiro for varicocele because with high orchidopexy and the consequent disappearance of venous stasis the true object of surgical treatment is completely attained. Orchidopexy is realized with ample exteriorization of the cord, which is freed from the vas deferens and describes a loop on the aponeurosis of the external oblique muscle, the latter being formed into a tunnel for the loop. This aponeurotic tunnel exerts a compression on the dilated veins which prevents stasis, in addition, it forms a kind of valvular system by intermittent compression and decompression resulting from efforts, orthostatic position, and ambulation. Isolation of the spermatic artery is unnecessary.

The operation is done preferably under local anesthesia. An incision is made as for inguinal hernia, it extends from the pubic spine to the inner side of the anterosuperior iliac spine. The cord is exteriorized down to the proximity of the testicle, the anterior aspect of the fibrosa and the cremaster is incised, and the vas deferens with its artery is isolated from the cord up to the external inguinal orifice. The fibrosa and cremaster are extirpated. The cord is applied to the aponeurosis of the external ob-

lique muscle in the form of a horseshoe with its opening facing downward and inward, and is fixed in place with six or eight No. 16 cotton sutures which pick up the aponeurosis on each side of the cord to form a tunnel for the latter. After verification of the height at which the testicle will be kept, the highest suture is inserted first. The sutures should not compress the cord as it should be able to slide freely inside of the tunnel. Orchidopexy is done after creation of the tunnel, but if desired the testicle may be fixed with a suture that catches the highest part of the vaginal tunic and the external pillar of the inguinal opening. The cellular tissue and Cooper's fascia are repaired with separate sutures of No. 40 cotton and the skin is closed.

After trying a number of procedures for the cure of varicocele, the author has limited himself to this method as it does not require dangerous ligations nor open the inguinal canal, but stops the reflux physiologically.

RICHARD KEMEL, M.D.

Epithelioma of the Scrotum ARCHIE L. DEAN, J. *Urol*, Balt., 1948, 60: 508

The author has recorded observations from the study of 27 patients with epithelioma of the scrotum. While the most common causative factor was prolonged exposure to petroleum and its products, other substances encountered in the various occupations, such as, tar, pitch, crude wool, and soot, demonstrated carcinogenic properties. Eight patients required scrotal cancers without exposure to industrial carcinogens.

In most cases a warty growth appeared on the most dependent portion of the scrotum after many years of exposure. In from 3 to 12 months it ulcerated and became painful.

The diagnosis may be suspected from a characteristic story, but it must be proved by microscopic examination. The great majority of the growths are squamous carcinomas of grade 2.

The only curative therapy for an epithelioma of the scrotum is wide surgical excision. Electrocoagulation and roentgen radiation have been found inadequate. When the scrotal tumor is removed a safety zone of normal tissue at least 1 cm. wide should surround the lesion on all sides. Sometimes the gubernaculum testis is infiltrated and one or both testes must be sacrificed.

Lungating primary tumors usually give rise to inguinal adenopathy but the enlarged groin nodes are not always cancerous. There is no evidence that removal of noncancerous regional nodes increases the chances of cure, and the operation is so often followed by considerable disability due to obstruction of the lymph channels that it should not be done unnecessarily. It seems characteristic of metastases from squamous cancers, whether of the scrotum, penis, or lip that early spread involves single nodes and causes them to enlarge and harden considerably so that it is easy to make a diagnosis of the metastases relatively early. It appears, therefore, to recommend that the inguinal metastases should

be demonstrated by aspiration biopsy before groin dissections are performed.

In no case in the author's study, when dissection of the regional nodes was not performed until histologic proof of their cancerous involvement had been obtained, did metastases subsequently develop beyond the groins. As soon as metastases have been discovered, radical dissections should be performed.

That epithelioma of the scrotum is a serious disease is shown by the fact that of the 27 patients observed only 5 lived 5 or more years after treatment.

FREDERICK A. LLOYD, M.D.

The Treatment of Cancer of the Penis (Sul trattamento del cancro della verga) BRUNO BERTICIA *Radiol. med.*, Milano, 1948, 34: 540

Thirty cases of carcinoma of the penis observed at the Instituto del Radio of Bologna between 1930 and 1946 were reported by the author. Seven of the patients were treated by combined surgery and irradiation and 18 by irradiation alone. Five of the first group and 5 of the second group were living 5 years after treatment.

Since the percentage surviving in both groups 5 years after treatment coincided almost exactly with the percentage surviving 3 years after treatment, it was concluded that the 3 year interval may be accepted as a criterion of cure, and that carcinoma of the penis treated by surgery plus irradiation carries a grave but not a hopeless prognosis.

EDITH B. FARNSWORTH, M.D.

MISCELLANEOUS

An Evaluation of Antiseptic Drugs and Antibiotics in the Treatment of Infections of the Urinary Tract. AUSTIN I. DODSON, *West Virginia M. J.* 1949, 45: 1

The author presents a brief review of the most important and interesting chemical and antibiotic preparations used to combat urinary tract infections.

Hexamethylenamine (methenamine, urotropin), although far less effective than the more recently developed urinary antiseptics, is still widely used. The bactericidal effect is dependent upon the elimination of formaldehyde in a strongly acid urine. A dose of 15 gr. three times a day was shown by Hinman to produce antiseptic bladder urine in 30 per cent of his cases. Twenty grains, four times a day, can usually be administered 4 or 5 days before there is evidence of irritation. Burning, with frequency of urination and the finding of red blood cells in the urine are indications for a rest period or a change to some other antiseptic.

Acridavine, serenum, pyridium, and hexylresorcinol have enjoyed brief popularity as urinary antiseptics. Hexylresorcinol and pyridium exert some analgesic effect upon the inflamed bladder mucosa; however, the bactericidal effect of the latter drug is not very impressive.

Mandelic acid is now universally recognized as a useful chemotherapeutic agent in the treatment of

urinary tract infections. Dodson continues to find mandelic acid useful in chronic infections of the urinary tract, and he uses it rather extensively, particularly in office practice. The drug is almost entirely free from toxic effects. Occasionally, after prolonged administration, a few hyaline casts and red cells may appear in the urine, but they promptly disappear when the drug is discontinued. Occasionally, the drug is nauseating and must be discontinued for that reason. It is not effective when renal function is poor or the urine cannot be kept acid in reaction.

No group of drugs has given greater promise as urinary antiseptics or has more nearly fulfilled that promise than the sulfonamides. Crystals of the drug precipitated in the renal tubules, and toxic manifestations are apt to occur when large doses of the drug are given and also when fluid intake is restricted. Therefore, high blood and urine concentration of the sulfonamides are not without danger. A free fluid intake and administration of alkalies are helpful in preventing renal complications. As these drugs are excreted principally through the kidney, it is necessary to have knowledge of the patient's renal function before their administration. Nausea, headaches, dizziness, and fever are the most frequent toxic manifestations. Skin rashes, episcleritis, and conjunctivitis occur more frequently with the use of sulfathiazole. Sulfadiazine and sulfacetamide are the most easily tolerated of the drugs.

While all sulfonamides are bactericidal to some extent for most bacteria, Alyea found that sulfathiazole was more bactericidal for staphylococci while sulfadiazine was of greatest use in the treatment of infection caused by pneumococci and Friedlander's bacilli.

Several investigators have found that sulfacetamide in the treatment of bacillary infections of the urinary tract deserves preference over the sulfonamides now in use. Lehr found that sulfacetamide compared favorably with other members of the group in bactericidal activity, that there was rapid renal elimination, therefore low tissue concentration in the presence of high urine levels, and the drug was highly soluble even in physiologic acid range of urine.

Sulfathalidine has been reported by Everett, Vosberg, and Davis to have produced excellent results in the treatment of *Escherichia coli* infections.

Sufficient time has not elapsed since the introduction of penicillin and streptomycin to adequately appraise their therapeutic usefulness in the treatment of infections of the urinary tract. Experience seems to indicate that both are more limited in their scope of usefulness than are the sulfonamides.

From the author's observation, neither penicillin nor streptomycin is to be advocated in the routine treatment of urinary tract infections. Infections with *Escherichia coli*, which represent approximately 60 per cent of those encountered in urinary tract infections, are cured as a rule with mandelic acid and sulfacetamide. Sulfadiazine and sulfathiazole are almost, if not quite, as effective against the gram positive cocci. These antibiotics have a definite ad-

vantage in acute infections, for these patients tolerate oral medication poorly. Fever and other toxic manifestations often subside rapidly following the administration of streptomycin or penicillin. These drugs (streptomycin and penicillin) are also useful as adjuncts to surgical treatment.

The treatment of infections of the urinary tract has been revolutionized by chemotherapy, for it is often possible to use specific drug therapy against specific organisms. The use of these preparations in complicated infections has been very helpful but cure is rarely obtained unless there is adequate renal function, free drainage, and absence of foreign bodies or devitalized tissue.

During the toxic period of acute infections alkalies may be counted upon to combat acidosis, lessen nausea and, at times, lessen bladder distress resulting from sensitiveness of the bladder mucosa to acid urine. A low urine acidity may have a deciding effect on the elimination of the infection for all organisms in the urinary tract except *Escherichia coli* and *Aerobacter aerogenes*. The acidity of the urine is a deciding factor in the bactericidal effect of mandelic acid and methenamine.

The most useful drugs for the acidification of urine are ammonium chloride, nitrohydrochloric acid and gluconic acid. Ammonium chloride should not be administered when the infection is caused by the urea splitting organisms. Patients with poor renal function should be closely observed when acidifying drugs are administered because of the danger of acidosis.

Laboratory facilities for the identification of bacteria and the determination of sensitivity to various germicides are not always available. It is possible, however, by careful observation, to judge fairly accurately the character of the predominating organism in most infections. It is well to remember that bacillary infections are more prevalent in the female than in the male, and that urine which is infected by the group of organisms found in the colon usually is acid, and that very cloudy urine which is persistently alkaline is apt to be infected with staphylococci or proteus bacilli. A stained smear of the centrifuged sediment is helpful in determining the type of infection that is present, and this can be an office procedure.

If the renal function is poor or the history and examination suggest the presence of calculi or obstructive disease, the value of chemotherapy alone may be disappointing. CONRAD A. KUEHN, M D

Streptomycin in Urogenital Infections JOHN K. LATTIMER, WILLIAM H. STEARNS, J. BURNS AMBERSON, JOSEPH SCHWARTZ, and Others. *J Urol*, Balt., 1948, 60: 974.

Twenty-five patients with urogenital infections were given daily intramuscular injections of 1.8 gm of streptomycin (0.3 gm every 4 hours) for a period of 120 days. Sixteen of these patients had been followed for a period of 1 year at the time of this report. Twenty-one of the 25 patients were found to have additional tuberculous lesions outside the genito-

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS MUSCLES, TENDONS, ETC

Osteoid Osteoma BRADLEY L. COLEY and NORMAN
IFENSON *Am J Surg*, 1949, 77 3

Brailsford, the distinguished British roentgenologist, regards osteoid osteoma as a low-grade cortical or subcortical bone infection, the authors, however, share Jaffe's opinion that the disease is a benign neoplastic lesion sui generis

The lesion appears as a small, ovoid, radiolucent, sharply circumscribed tumor surrounded by bone sclerosis in a male child whose average age is 13 7 years The site of predilection is predominantly in the lower extremities

Differential diagnosis should include the following diseases: osteomyelitis of the chronic sclerosing type, Brodie's abscess, periostitis, osteogenic sarcoma, Ewing's sarcoma, and bone repair following a greenstick fracture Great difficulty may be encountered in differentiating osteoma from Brodie's abscess, roentgenologically

Studies of blood chemistry, serology, and bacteriology have yielded no significant abnormalities in osteoma

The treatment is surgical removal en bloc of the entire nidus X-ray irradiation has not been practiced by the authors in the 10 cases herein reported

The article is accompanied by many excellent roentgenograms and one photomicrograph of the osteoid osteoma obtained from one of the cases

SAMUEL L. GOVERNALE, M D

Granuloma of the Bones (Granulomes des os) L
TAVERNIER *Lyon chir*, 1949, 44 41

The author presents a few cases of eosinophile granuloma, a disease not well known in France A 28 month old boy had a lesion in his femur The roentgenogram did not resemble any that the author had seen before Exploration revealed thickening of the periosteum and the lesion was filled with a soft red tissue which was easily curetted The microscopic examination revealed a certain type of granulomatous tissue Five months later the lesion was healed

Another case was diagnosed as osteogenic sarcoma This lesion responded very favorably to x-ray therapy and finally healed The biopsy specimen of this lesion was diagnosed as a fibrous osteitis The final study revealed an eosinophile granuloma with radiation changes

The third case was that of a 9 year old boy who had a cystlike lesion in the intertrochanteric area The biopsy material resembled lymphosarcoma There were no Steinberg cells (Dorothy Reed cells) A pathological fracture occurred which did not heal There was shortening of the extremity with loss of bone substance Because of the complete lack of

callus, bone grafting of the fracture site was done Healing occurred and left a shortening of 2 cm

The author then discusses the differential diagnosis of this unusual condition and mentions granuloma mycosis, fetal splenohepatic disease, Letterer-Siwe disease, and Hand-Schuller-Christian disease He opposes the idea that Hand-Schuller-Christian disease and eosinophile granuloma are the same disease because in the former the patient usually dies while in the latter the condition usually heals

GEORGE I. REISS, M D

Causation and Treatment of Painful Stiff Shoulder
Subdeltoid Bursitis, Periarthritis, Tendinitis,
and Adhesive Capsulitis HENRY W. MYERDINE
and JOHN C. IVINS *Arch Surg*, 1948, 56 693

The clinical observations in 150 consecutive cases of stiff painful shoulder, in which manipulation under anesthesia, surgical excision of calcified plaques or bursas, injection or needling was performed at the Mayo Clinic during the years 1942 through 1946, form the basis for this study Detailed reports of 9 cases are included in this article to illustrate certain points of diagnosis and treatment It should be pointed out that statistics vary according to the type of practice The majority of patients with painful stiff shoulders seen by the general practitioner are acutely disabled from some undue strain or exposure, whereas the orthopedic surgeon in his consulting practice usually sees patients who have a chronic condition attended by more or less atrophy of disuse The condition in the authors' cases was essentially of the latter type

In this study, 52 of 150 patients (35 per cent) were male and 98 (65 per cent) were female The duration of symptoms varied from 7 days to 12 years, 65 per cent of the patients had trouble for less than 1 year and 54 per cent had trouble for less than 6 months There was a definite history of trauma in 36 of the cases (24 per cent), and in 6 cases (4 per cent) there was a history of antecedent systemic infection In the remaining 108 cases (72 per cent), in which the onset apparently was gradual and the course was intermittent, the causative factor was not ascertained In this series of cases the urinalysis gave negative results, the results of flocculation tests for syphilis were negative in all cases, the sedimentation rate was rarely elevated, and the concentration of hemoglobin and the leucocyte counts were within normal limits in all cases Roentgenographic examination revealed calcification in 59 cases (39 per cent), osteoporosis in 34 cases (23 per cent), and nothing abnormal in 57 (38 per cent) Since the evidence of calcification depends on the degree of deposit, calcification doubtless was present in more cases than mentioned because a certain percentage of patients do not show evidence of calcification at the time of examination although it may have been

present at a previous time. We have seen patients in whom calcification appeared and disappeared with or without treatment. In other words, the calcification may disappear spontaneously.

Pain, stiffness, and local tenderness were the characteristic symptoms, and they often followed some heavy undue exertion, such as gardening, painting, and washing walls. The pain was usually intermittent, aggravated by movement, and often worse at night. It was occasionally so severe that opiates were required for relief. At times it was referred down the arm and into the hand, so that neuralgia was the principal presenting complaint. Commonly the pain extended upward into the side of the neck. The stiffness was principally a limitation of abduction and rotation, to a variable degree. The frozen shoulder was held in the sling position and permitted no motion except some apparent forward flexion and backward extension as a result of movement of the shoulder girdle. Nineteen per cent of the patients gave a history of bilateral involvement or the subsequent development of a similar condition of the second shoulder.

In all cases of painful stiff shoulder a detailed history of the illness should be obtained. The next essential procedure is a complete physical examination. A roentgenographic examination of the shoulder should always be made to rule out arthritis, fracture, or the presence of organic bone disease, such as infection or primary or metastatic tumor, and to give evidence of the degree of osteoporosis or tendinous calcification present. In many cases there is decided osteoporosis, especially of the greater tuberosity and the anatomic neck of the humerus.

Tuberculosis of the shoulder joint may be confused with a frozen shoulder in the early stage of the disease because both pain and stiffness are present, but as the tuberculosis progresses the destructive changes indicate its true nature. The persistent temperature, gradual onset, progressive severity of symptoms, atrophy, and frequent presence of a primary tuberculous focus should make the physician suspect tuberculous arthritis of the shoulder. It is difficult to produce ankylosis, and it seldom takes place in tuberculosis, surgical operation, with prolonged fixation, is necessary. In cases of frozen shoulder, stiffness may develop within a few days of the onset of pain, in spite of treatment for relief of pain, but true bony ankylosis is rare. Adhesions can be broken by manipulation and a satisfactory functional result obtained, but in tuberculosis, once the destructive changes have occurred, action of the joint is permanently lost. The roentgenographic examination is of value in the diagnosis. With the exception of bony atrophy and regions of calcification described in frozen shoulder, the joint appears to be normal. In tuberculosis of the joint, however, roentgenograms reveal atrophy and later destructive arthritis with areas of absorption in the head of the humerus. Aspiration or excision of tissue for microscopic study may be needed to clarify the diagnosis as a final measure in perplexing cases.

Tuberculous bursitis produces a bulging soft mass which may contain palpable rice bodies. Such bursas usually are anterior to the shoulder. Careful dissection and complete excision will cure many of these tuberculous lesions, and the results will be improved by the administration of streptomycin.

Acromioclavicular separation follows severe injury and may be differentiated from frozen shoulder by the looseness of the joint on palpation. In complete separation a diagnosis may be made by mere inspection and demonstration of false motion, the roentgenograms will reveal wide separation of the articular surfaces, and a definite sulcus or depression also can be seen. In the acute stage of acromioclavicular arthritis local tenderness and swelling are present, in the chronic stage destructive or hypertrophic changes usually are revealed in the roentgenograms.

In cases of fractures of the glenoid cavity there is a history of trauma, and the roentgenograms should reveal an area of separation.

Fractures of the greater tuberosity of the humerus, with or without dislocation, may be recognized on palpation and by roentgenographic study.

Ruptured supraspinatus tendons do not cause fixed or frozen shoulders, nor is the pain on movement as severe as in the presence of frozen shoulder. The patients have ability to move the shoulder, but abduction causes pain and the patient may not be able to bring the arm up beyond a right angle.

Infection of the shoulder joint or osteomyelitis involving it should offer little difficulty in diagnosis, since it is accompanied with temperature locally and generally, an increased leucocyte count, and is roentgenographically visible.

Tumors do not cause symptoms of pain and stiffness unless they are of great size, and then clinical and roentgenographic evidence will reveal changes in the bone.

The patient with the acute stage of the disease or with intense pain, local tenderness, slight fever, and who keeps his arm at the side for protection may be treated for a few days at home by rest in bed, local application of heat, increased intake of fluid, and maintenance of elimination and traction, together with the administration of adequate anodynes. Abduction should be encouraged, and conventional diathermy and roentgen therapy may be used, after which patients who have painful stiff shoulders often are relieved of their symptoms. When the patient is seen with the disease in the subacute recurring stage, after much of the pain has subsided, and residual soreness and stiffness aggravated by movement persist, further examination should then be made to exclude calcification, traumatic lesion, or tumor. Conventional diathermy, radiant heat, stretching, and active and assistive exercises should be carried out routinely. If there is difficulty in obtaining abduction, traction may be employed or manipulation followed by abduction treatment in a splint or cast. In cases in which definite swelling of the bursa occurs as a result of

is probably due to a common etiological factor, possibly avascular necrosis. Coxa vara associated with multiple congenital deformities is not the same lesion as that with which the article is concerned. Subtrochanteric osteotomy at about 6 to 8 years of age with wide abduction of the distal part of the limb is the treatment of choice.

Tuberculosis of the Greater Trochanter and Trochanteric Bursae ALBERT AHLBERG *Acta chirurgica*, 1948, 97: 201

During the period from 1928 to the middle of 1947, 127 patients (83 men and 44 women) with tuberculous bursitis or osteitis in the trochanteric region were treated by the author. These constituted 13 per cent of the cases of bone and joint tuberculosis treated during the corresponding period. Of these, 14 patients had had a tuberculous infection in another part of the body before the process in the trochanter developed, 44 had other tuberculous foci concurrently with the trochanteric process, and 20 patients developed tuberculosis in some other part at a later date, in 14 of the last-mentioned cases (11.02 per cent) the later process consisted in involvement of the hip joint of the same side. In 87 cases extirpation of the bursa and excision of the diseased bone in the trochanter was carried out. Sixty-one men and 35 women were discharged as cured after their first period in the hospital. Seventeen men and 5 women had small sinuses in the process of healing. Ten men and 3 women had small sinuses in the process of healing. Ten men and 3 women who had only trochanteritis with running sinuses died, 1 of the men dying of amyloidosis.

A follow-up examination of the patients who had been discharged more than a year previously revealed that 71 patients were cured and 6 had small sinuses almost completely healed. Eight men and 3 women who had been discharged less than a year previously were cured, and 2 other men had small sinuses. Two female patients who were cured and 4 men and 2 women with small sinuses were still in the hospital.

The x-ray films show, in addition to decalcification, either a subcortical focus or caries with small defects in the cortical outline. Sequestrumlike calcareous shadows in the soft tissue are often seen outside of the greater trochanter. According to Stracker, the tendons have loosened from their insertion on the greater trochanter because of the tuberculous process in the bone, with the result that a small necrotic bone fragment together with a small piece of the necrosed tendon works loose.

Most of the patients with bursitis or trochanteritis were extremely troublesome to treat. In instances in which there were other tuberculous foci in the pelvis or the lower part of the spine, and an abscess had penetrated downward causing secondary infection of the trochanteric bursa, particular difficulty in treatment was encountered.

Whenever there is an affection in the region of the greater trochanter, tuberculosis should be imme-

diately suspected and examinations at once undertaken so that a radical operation may be carried out without delay if this condition is found. The course of the disease would then probably be shortened, since the process would not have time to spread to such an extent as to cause difficulties in treatment.

C. FRED GOERINGER, M.D.

Ischaemic Necrosis of Anterior Tibial Muscles J. ROWLAND HUGHES *J. Bone Surg.*, 1948, 30-B: 581

Ischemic necrosis of the lower limb muscles is well recognized as a complication of injury and recorded cases show that, as in the upper extremity, isolated muscles or muscle groups may be affected. Traumatic ischemic necrosis of the anterior tibial group of muscles may thus occur, but it is less widely appreciated that such necrosis may also arise when there has been no injury at all.

The author reports 3 cases of ischemic necrosis of the anterior tibial muscles which were not due to injury. In 2 of these, ischemia was the result of strenuous or unaccustomed exercise in young males, in the third case it was an incident in a systemic disturbance. In all 3 cases the condition probably was the result of spasm of a large segment of the anterior tibial artery.

During the first few hours the clinical features resemble those of tenosynovitis of the tibialis anterior, and after 12 to 24 hours, those of cellulitis of the leg. Later there is "drop foot" due to muscle weakness, contracture limiting plantar-flexion movement, and woody hardness of the muscles in the middle third.

The morbid histology is similar to that of Volkmann's ischemic contracture.

The possible explanations—primary arterial disease, arterial occlusion by pressure of the interosseous membrane, occlusion by tension with the fascial space, intraluminal occlusion by embolism or thrombosis, and fatigue arterial spasm—are discussed. It is concluded that the most likely cause of the necrosis is spasm of the anterior tibial artery due to muscle fatigue, aggravated by increased tension within the anterior fascial compartment due to reaction after strenuous exercise.

The object of treatment should be to relieve arterial spasm before necrosis supervenes. Early injection of eupaverine might be helpful. Assuming that the patient is seen within the first 12 hours, exploration appears to be warranted.

The operative approach should be between the muscles rather than through them. Care must be taken to avoid damage to intramuscular branches. The fascia cruris should not be repaired. If there is arterial spasm the appropriate treatment should be employed, but arteriotomy should be limited to resection of a very small segment, the part of the anterior tibial muscle which will be deprived permanently of its blood supply is directly proportionate to the length of arterial segment excised. The danger of exploring muscles after necrosis has supervened cannot be over-emphasized.

Whatever treatment may be undertaken during the first 24 hours, the limb should be supported with the ankle in the midposition and free from constriction. This position should be maintained until the acute inflammatory reaction has subsided and until there is no longer any tendency to further contracture. Subsequently a toe-elevating spring should be worn for the first few months of weight-bearing. Surviving muscle fibers should be redeveloped by graduated exercise.

Although not previously recognized, evidence is shown that regeneration of necrotic muscle is possible in the human being.

RUDOLPH S. REICH, M.D.

Rupture of the Achilles Tendon (*Ruptura del tendón de aquiles*) ENRIQUE MALLO *Sem méd*, B. Air, 1948, 55 Supp. 2863

Rupture of the Achilles tendon may be complete or incomplete, transverse or oblique. The tendon may be pulled away from the calcaneus or part of the bone fractured and attached to the disrupted tendon. The treatment depends upon the conditions presented. Immobilization without surgery is not satisfactory in most instances. Prolonged immobilization after surgery is equally as bad.

The author believes that after from 10 to 14 days, active motion should be permitted, particularly in the patients in whom his operative procedure has been done. This consists in sectioning of the long plantar muscle and reflection of an outer leaf of the Achilles tendon. The muscle is attached diagonally across the Achilles tendon and anchored to its lateral border, after which the dissected leaves are replaced to enclose the plantar muscle.

The results have been most gratifying from the viewpoints of early ambulation, utility, and strength of the tendon.

STEPHEN A. ZIEMAN, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Arthrodesis of the Wrist Joint by the Technique of Smith Petersen (*Artrodesis de la muñeca según la técnica de Smith Petersen*) OSCAR R. MARÓTTOLI *Rev. orlop. traumat.*, B. Air, 1948, 18, 20

The technique of Smith Petersen was used in 2 cases of spastic pronation and flexion paralysis of the arm. One case was that of a 16 year old girl with a birth injury to the plexus at the shoulder. The deformity was that of flexion contracture of the hand resulting from paralysis of the extensor muscles. The second case was that of a 15 year old boy with infantile spastic paralysis of the hand in flexion. In this case the pronator syndrome could not be modified by any form of training.

In the young girl an excellent functional and esthetic result was evident a year after operation. The prehensile movements of the fingers showed a fine degree of extension and flexion, and pronation and supination of the hand were complete. In the boy, 6 months after the operation, the hand could be

closed to a fist with excellent force and the hand could be supinated to 90 degrees. In this case it was impossible to predict what other procedures would be necessary to obtain satisfactory results because this type is a complex paralytic residua.

The technique of the operation consists in a bayonet incision beginning about 6 cm. above the ulnar styloid and extending on the lateral border of the ulnar shaft to and across the wrist and then parallel to the metacarpal bone for about 3 cm. An osteotomy of the ulna is then done at a point 3 or 4 cm. above the ulnar styloid and the distal portion of this bone is excised to leave the lateral surface of the radius exposed. The articular cartilaginous surfaces of the radius and the first row of carpal bones is then removed. Toward the dorsal surfaces of these bones two holes are bored to receive the bone implant cut from the excised portion of the ulna. The remaining chips and spicules of the ulnar implant are then inserted into the remaining radiocarpal space and the tissues are closed in layers.

With completion of the operation the hand is put up in plaster in a position of moderate extension at the wrist and in exaggerated supination. After 3 months in the cast, it is removed and re-education is initiated.

JOHN W. BRENNAN, M.D.

Approach to and Exposure of the Hip Joint for Mold Arthroplasty M. N. SMITH PETERSEN *J. Bone Surg.*, 1949, 31-A, 40

A joint has two surfaces which must be so shaped as to permit function without interference or impingement through the greatest possible arc. Consequently, in the case of the hip joint, it is necessary to expose the acetabulum and its adjacent structures, as well as the femoral head and neck. In the past the various approaches to the hip joint have failed to expose the acetabulum properly, and the surgeon's efforts have been directed mainly at partial reconstruction of the femoral head. Reconstruction of the acetabulum demands intrapelvic exposure of this side of the joint. The approach to such an exposure necessitates extensive dissection. Since this can be carried out along structural planes, it is not destructive.

The exposure described is an extension of the hip joint approach previously described by the author. The refinement is essentially exposure of both the medial and lateral sides of the anterior third of the ilium and the anterior acetabulum, plus osteotomy of the anterior inferior iliac spine and the anterior acetabular wall. Utilization of this approach facilitates dislocation of the hip as well as reconstruction of the acetabulum.

The purpose of the operation is to create a joint with approximately normal mechanics. This supplies the clue to fitting of the mold. Normally, joint surfaces glide over one another with a minimum amount of friction, consequently, the mold must be loosely fitted so as to allow the greatest possible range of motion between it and the adjacent, reshaped surfaces of the femoral head and acetabulum.

Fig 1 (Nicola) Shoulder reduced by traction and adduction with fist high in the axilla

The author recommends testing the range of motion before wound closure which enables him to determine the optimum postoperative position and the proper exercises to be used later. His experiences lead him to conclude that diathermy cauterization of the edges of the new acetabulum diminishes the tendency of bone proliferation and spurring. Closure of the wound is made along fascial planes with normal tendinous relationships. Nine excellent drawings elucidate the technical details.

KENATH H. SPONSEL, M.D.

FRACTURES AND DISLOCATIONS

Acute Anterior Dislocation of the Shoulder TOUFFICK NICOLA *J Bone Surg*, 1949, 31-A 153

The author has, in the past 6 years, operated upon 22 acute dislocations of the shoulder and found that the location and extent of the injury vary with the mechanism producing it. The observations include 5 cases previously reported, making a total of 27 cases. In most of the cases studied, the capsule and labrum had been torn from their attachment to the periosteum of the scapular neck. When hyperabduction produces the injury, the capsule and more or less of the subscapularis are torn from the humerus. Two such cases were reduced only after the torn flap had been lifted from the glenoid cavity where it had been sucked.

Downward traction and adduction with the fist high in the patient's axilla is the most satisfactory and least traumatic means of reducing the dislocation as observed in this series of cases. Five of these patients suffered redislocation probably from too

Fig 2 (Nicola) Apparatus which prevents redislocation by restricting abduction and external rotation

early vigorous use of the shoulder before capsule reattachment was secure. Tunnelling the long head of the biceps and the coracohumeral ligament through the humerus gave permanent relief.

Restraint of external rotation and abduction for 8 weeks gives optimum results. The apparatus shown by the author accomplished this well.

FRANCES E. BRENNER, M.D.

The Treatment of Recent Dislocations and Fracture Dislocations of the Shoulder HENRY MILCH *J Bone Surg*, 1949, 31-A 173

In the light of present knowledge, the treatment of acute dislocation of the shoulder by the Kocher manipulation, as described in 1870, proves not only unphysiological but risks fracture of the shaft. When the humerus hangs alongside of the trunk, the muscles about the shoulder girdle pull in various directions with the principal resultant in a medial direction. If the tensile strength of the bone is less than the combined medial muscle pull, Kocher's maneuver results in an oblique fracture between the tuberosities.

When the arm is fully abducted to the overhead position, all the shoulder girdle muscles run in the line of the humeral shaft. Muscle antagonism is then overcome by the same line of pull needed to reduce the dislocation.

The technique of reduction based on this position is simple. With the patient supine, the dislocated humeral head is firmly fixed by the surgeon's hand and the arm is gently brought to the overhead position when the head can be gently pushed over the glenoid rim. This can be accomplished so gently that anesthesia is rarely needed, and injury to the vessels or nerves has not been encountered in 10 years' use of this measure.

Prereduction check for nerve involvement is as essential as roentgenograms to rule out fracture of the glenoid or the greater tuberosity. In the presence of fracture, this same maneuver safely effects reduction and alignment of the fracture. It was described by Sir Robert Jones for this purpose.

In simple dislocations, a "check rein" to prevent abduction and external rotation is the optimum dressing. When fracture is present, motion must be restricted by a hanging plaster, Velpeau bandage, abduction splint, or traction until consolidation occurs.

Open Reduction and Internal Fixation of Fractures of the Long Bones

HARRISON L. McLAUGHLIN, SAWNIE R. GASTON, CHARLES S. NEER, and FRED ERICK S. CRAIG. *J. Bone Surg.*, 1949, 31-A: 94.

This article deals with 200 consecutive shaft fractures of the tibia and femur treated by open reduction and internal fixation. Sixty-five patients were operated upon in spite of the fact that the same result might have been anticipated from the use of other methods of treatment; 57 were operated upon because no other type of treatment was suitable; 78 patients presented compound fractures.

The percentage of patients immobilized after operation, the percentage of physiological function maintained, and the percentage of cases in each category in which there was protected early weight bearing are given in table form in the original article. The table covers 179 consecutive shaft fractures. Immobilization was not used after operation when it was not indicated. There were 7 cases of nonunion in the tibia, and 1 case of loss of fixation in the femur. Among 179 shaft fractures there were 15 extremities which were short, the greatest amount being 3 cm., and there were 5 cases of visible angulation. Among the 179 shaft fractures there were 12 cases of fractures of the tibia in which there was limitation of the adjacent joint, and there were 17 cases of fracture of the femur in which there was limitation of the adjacent joint. Among the 179 shaft fractures, 131 cases were asymptomatic.

Among 121 cases of fractures of the tibia, the average time of economic recovery with full normal activity was 5.7 months. In 58 cases of fracture of the femur, the average time of economic recovery was 6.5 months. It was thought that the good results depended more upon the way the materials for internal fixation were used than upon their composition.

The Treatment of Complicated Inflammatory Processes of the Elbow Articulation (Zur Behandlung schwieriger Ellbogengelenkentzündungen)

HEINRICH WESTHUES. *Chirurg*, 1948, 19: 545.

Metal plates and a so-called wire extensor allow the application of tension to wire within and outside of a cast for inflammatory processes of the elbow, and also the immobilization of the wire without the use of metal extension arches. This method is useful particularly when the time element is of importance and

Fig. 1 (Westhues) a, Metal plate, b, wire extensor, c, the main part of the cast with the arm support, d, beaded wire, e, complete dressing, f, transverse section through the supporting apparatus, f', section through the arm, f'', section through the support, f''', cast.

the working conditions are primitive, for instance, in advanced positions on the battlefield.

Both shoulders should be included in the body cast, into which a wooden plank, 2 cm. thick, 5 cm. wide, and from 20 to 25 cm. long, is incorporated. After the application of the body cast, plaster of paris is applied to the forearm and the hand. On the dorsal side this cast reaches the proximal phalanges of the fingers, but on the volar side it extends to the middle phalanges to prevent premature movements of the fingers and also flexion contractures. A stab wound is made and a beaded wire is carried through the olecranon so that the bead is in contact with the bone. The cast surrounding the hand is attached with plaster of paris to the support protruding from the body cast. Two wooden planks, 1.5 cm. thick, 35 cm. long, and 4 cm. wide on one end and 2 cm. wide on the perforated end, are applied so that the narrow ends are slipped over the ends of the wire, while the wide extremities are attached to the support with plaster of paris.

After the cast is hardened, tension is applied to the extension wire by means of the wire extensor. The two metal plates immobilize the wire.

The apparatus provides immobilization of the injured elbow without interfering with the accessibility of the articulation. The arm needs no support and therefore one person is able to change the dressing. Further operations can be performed if necessary, without removal of the apparatus.

The apparatus is recommended by the author for grave injuries of the elbow accompanied by severe trauma of the soft tissues, because the frequently resulting phlegmon is easily accessible. However, the apparatus should not be used if the bones in the region of the articulation are completely destroyed.

The Treatment of Fractures of the Metacarpals
(Tratamiento de las fracturas de los metacarpos)
SILVANO MONDOLFO and VICENTE A. MOLINA *Rev orlof traumat*, B. Air, 1948, 18, 32

The material on which this report is based consists of 157 cases of simple, or closed, fractures and 20 cases of open, or complicated, fractures.

Of the simple fractures, 32 involved the second metacarpal, 21 the third, 21 the fourth, and 64 the fifth. In 19 instances the breaks were multiple. There were 31 fractures of the base of the metacarpal, 69 of the shaft, and 51 of the distal end (head, or subcapital fractures of Roemer).

In 140 of the closed fractures the displacement was slight, and these were treated by manual reduction and immobilization in plaster. In the base involvements, the cast included the first phalanx of the corresponding finger. Results are evaluated on the basis of 98 of these patients who could be followed up and in whom the late results could be observed. In these 98 cases there were 50 optimal, 27 good, 12 mediocre, and 9 poor anatomical results, and 61 optimal, 31 good, 3 mediocre, and 3 poor functional results. Thus, the functional results were better, on the whole, than was promised by the anatomical conditions after healing. In the basal and diaphyseal involvements the functional and anatomical results accorded rather well, however, in fractures of the head of the metacarpal the functional results were so much better than the anatomical results that there was a sharp contrast to those in the other two fracture locations. The better functional results in fractures of the head are tentatively explained on the basis of the more rapid consolidation of the subcapital fractures, the basal lesions required, on the average, 37 days for consolidation, those of the shaft 31 days, and those of the head 26 days.

In the more marked types of displacement which consisted, as a rule, in angulation toward the palm, and which were more frequent in the oblique type of fractures of the shaft, other types of treatment were at times attempted. In 11 instances traction was tried by means of a thread passed through the pulp of the fingers, this form of traction was painful, at times produced trophic disturbances of the finger pulp tissues, and was not very effective. Skeletal traction by Kirschner wire through the basal phalangeal bone tended to correct the over-riding of the fragments but failed to correct the lateral displacements. The results with regard to the residual stiff finger were unsatisfactory, despite the fact that the wire used was only one-third of a millimeter in diameter. Four cases were treated surgically. One patient with a subcapital fracture of the fifth meta-

carpus was osteotomized with immobilization in a plaster cast, the result was poor. A second patient with fracture of the second and fourth metacarpals who was treated by excision of the proximal fragment had a poor result. A third patient with subcapital fractures of the second, third, and fourth metacarpals who was treated by the osteosynthesis of Lambotte had a poor result. The fourth patient with comminuted fracture of the head of the second metacarpal was treated by resection of the head of the bone and had a poor functional result. In these more severe displacements of the closed fracture of the metacarpals the best treatment would seem to be the best possible correction by the method of Jahss (traction and manipulation by grasping the basal phalanx), with a modeled cast fitting closely to the dorsal surface of the fractured bone.

In the various types of open fracture, results from the functional standpoint were, on the whole, not good. In 1 of the 20 cases of open fracture an amputation of the finger was performed. In 4 cases infectious complications developed, requiring in 2 instances the amputation of the hand, and in 1 case the amputation of the finger. In the fourth case osteomyelitis developed and the condition healed with a pseudarthrosis. Finally, in 1 patient gangrene of 3 fingers developed which required their amputation. Of the remaining 14 patients with open fracture, 9 were treated by manual reduction with plaster immobilization, 3 by open reduction and plaster, and 2 by skeletal traction. Neither the anatomical nor functional results were satisfactory following any of these methods of treatment. The results in the healing of the soft tissues in these open fractures have improved with the advent of the newer drugs for combating infection, without, however, bringing any apparent improvement in the functional results.

The authors agree with Waugh and Ferrassano, that fracture of the metacarpal bones is a serious lesion and one requiring more attention than has previously been allotted to it.

JOHN W. BRENNAN, M.D.

Cough Fracture in Late Pregnancy J. W. PAULLEY, D. H. LEES, and A. C. PEARSON *Brit M J*, 1949, 1, 135

A study of the anatomy and fracture sites in the majority of pregnant patients suggests that the shearing stress occurs along the line between the origin of the external oblique muscle (from the lower four ribs) and the costal slips of the latissimus dorsi. This, however, ignores the long back muscles, the sacrospinalis. In the pregnancy stance the head and shoulders are thrown back, compensatory to this is a lordosis involving increased postural tone, and perhaps hypertrophy of the iliocostalis and longissimus portions of the sacrospinalis. Inco-ordination or action of more than normal violence might occur in this muscle in such circumstances. Thus forcible expiration, as in coughing with depression of the lower ribs by the iliocostalis, could provide con-

ditions for a shearing stress sufficient to fracture a rib. Another possible mechanism is that the uterine mass is driven backward and upward against the inner surface of the lower chest in coughing by contraction of the anterior abdominal muscles. If bone fragility can be excluded the remarkable incidence of fracture of the lower ribs, consistently on the left side in late pregnancy, could be due to a mechanical cause peculiar to the abdominal mass or compensatory lordosis.

Another possible etiological factor is the likelihood of fracture when the serratus is taut at the time of coughing, as it may be when the arm is raised or when the patient is resting on one elbow.

The treatment advocated is adequate strapping of the chest, which gives these patients considerable relief.

There are relatively few cases of this condition reported in the literature. From a study of these cases and the 4 patients in their own series the authors noted the following common findings: (1) cough fractures occur late in pregnancy, (2) they tend to be on the left side, (3) the lower ribs are chiefly involved, and (4) multiple fractures are the exception.

C. FRED GOERINGER, M.D.

Cough Fracture of the Ribs RAYMOND C. COHEN *Brit. M. J.*, 1949, 1: 133

The author was able to collect 7 cases of so-called cough fracture of the ribs. The literature on the subject was said to be scanty. Howson (1934) was able to trace 58 reported cases.

It is probable that the fractures of the ribs are due to muscular action on areas of rarefaction in the ribs. The upper five ribs are more unlikely to fracture from cough because they are shorter and are supported posteriorly by the scapular musculature.

C. FRED GOERINGER, M.D.

Treatment of Suppuration of the Hip Joint Following Injuries by Firearms (Zur Behandlung der Hüftgelenkseiterungen nach Schussverletzungen) EMIL WITTMOSER and ERICH DANGSCHAT *Chirurg*, 1948, 19: 546

Experience gained from the treatment of 46 patients with suppurative processes in the hip joint following injuries by firearms led the authors to the following conclusions:

There are three methods of treatment of such conditions: (1) partial resection of the femoral head, (2) total resection of the head which may be supplemented by resection of the neck or a portion of the shaft of the femur, and (3) exarticulation.

The first method furnished in 23 cases an excellent exposure of the articulation and ideal drainage at the deepest point. An oblique incision is made through the gluteus maximus muscle and the upper margin of the quadratus femoris. The leg is kept in a position of internal rotation and flexion. A part of the femoral head is resected from its lower, posterior portion. The adjoining rim of the acetabulum may also be removed. As the body cast interferes with early

detection of a phlegmon, the leg is placed, after the operation, on a metal splint in a position of abduction and external rotation, and slight extension is applied to it. After the fever subsides, usually after 4 or 5 weeks, a body cast is applied for approximately 5 months. Occasionally a wire extension may be employed. Of the 23 patients treated by this method 4 succumbed to septicemia.

The most popular method, namely, total resection of the femoral head, was employed in 14 patients. The author uses it only when the head or the neck is completely destroyed. He employs the same approach as that used for a partial resection because it creates better conditions for drainage than the anterior route. The latter is recommended only when the port of entry lies anteriorly. It should be supplemented by a posterior incision to allow the introduction of a drain through the entire thickness of the hip. The leg is placed in a metal splint and extension is applied. After from 4 to 6 weeks, when the fever subsides, the free femoral end is placed in the acetabulum and a fenestrated body cast is applied for approximately 7 months. Of the 14 patients operated upon in this manner, 5 died from septicemia.

In 9 cases an exarticulation could not be avoided. Four patients died. JOSEPH K. NARAT, M.D.

The Treatment of True Congenital Dislocations of the Hip (Etat actuel du traitement des luxations congénitales de la hanche) JACQUES LEVEUF, PIERRE BERTRAND, and HENRI GUIAS *Rev. orthop.*, Par., 1948, 34: 347

The authors differentiate between true dislocations and subluxations.

Dislocations are characterized by the interposition of soft parts between the femoral head and the acetabulum. Closed reduction, as a rule, is almost impossible and necessitates an operation in most instances.

Subluxations are characterized by the absence of interposing soft tissue. The femoral head is usually larger which makes it impossible for it to articulate properly with the acetabulum. In these cases closed reduction is possible and the results, as a rule, are excellent. Open reduction is very satisfactory in young infants, and the only complication of any consequence is epiphysitis of the femoral head which results in change of the shape of the femoral head. This complication was found in 24 per cent of the cases.

GEORGE I. REISS, M.D.

Roentgenographic Changes in Nailed Slipped Capital Femoral Epiphysis ARMIN KLEIN, ROBERT J. JOPLIN, JOHN A. REIDY, and JOSEPH HANELIN *J. Bone Surg.*, 1949, 31-A: 1

The authors present a roentgenographic survey and clinical evaluation of 51 cases of nailed slipped capital femoral epiphysis previously reported in 1947. Reported are 31 cases, 4 of which presented bilateral involvement, in which all hips were nailed *in situ* because the amount of slipping had been less

The apparatus is recommended by the author for grave injuries of the elbow accompanied by severe trauma of the soft tissues, because the frequently resulting phlegmon is easily accessible. However, the apparatus should not be used if the bones in the region of the articulation are completely destroyed.

Roentgenographic Changes in Nailed Slipped Capital Femoral Epiphysis ARMIN KLEIN, ROBERT J. JOPLIN, JOHN A. REIDY, and JOSEPH HANELIN *J. Bone Surg.*, 1949, 31-A: 1

The authors present a roentgenographic survey and clinical evaluation of 51 cases of nailed slipped capital femoral epiphysis previously reported in 1947. Reported are 31 cases, 4 of which presented bilateral involvement, in which all hips were nailed *in situ* because the amount of slipping had been less

than 1 cm. After an average follow-up period of 32 months, the average index of motion was 90 per cent of normal, and the average percentage of normal hip function was 96.

Early mobilization and active weight bearing on crutches within 2 or 3 weeks after operation promote preservation of the physiological function of the hip. In this series of cases, in which nailing was done *in situ*, traumatic arthritis or aseptic necrosis of the femoral head has not occurred.

Sixteen patients were reported with marked slipping (more than 1 cm). They were treated by arthrotomy, osteotomy through the epiphyseal plate, replacement of the head to its anatomical position in relation to the neck, and lateral nailing for fixation. After an average follow-up period of 33 months, the average index of motion was 85 per cent of normal, the average percentage of normal hip function, 92.

To obtain early motion, active weight bearing on crutches is permitted within 2 or 3 weeks after operation. Two additional basic requirements are necessary to obtain the results shown: (1) sufficient exposure should be obtained to permit replacement of the head, and (2) the hip joint should be entered through an incision across the capsule over the anterior portion of the epiphyseal plate. This spares the ligamentum teres and the posterior, superior, and inferior portions of the visceral capsule. The osteotomy is performed through the epiphyseal plate, which is avascular, no part of the neck being sacrificed. These details minimize the possibility of damage to the circulation of the head. Thus, the head is replaced to its normal position, its margins draped anteriorly and laterally beyond the neck, with a minimal amount of damage to the epiphyseal circulation. Two incidents of traumatic arthritis were encountered in the follow-up. Faulty performance of the operations was contributory.

The authors have noted roentgenographic evidence of fusion of the epiphysis within 4 to 8 months after nailing in the open reduction cases and within 6 to 18 months in the cases nailed *in situ*. In the latter group, the nailed epiphysis fused 8 to 21 months sooner than the epiphysis on the uninvolved side. With open reduction, the nailed epiphysis fused 5 to 35 months before the epiphysis on the uninvolved side. The nail should extend well into the head. In 4 cases nailed *in situ*, growth continued beyond the end of the nail. In 2 cases with slipping of more than 1 cm, nailing *in situ* was performed. By the authors' present criteria, these cases would have open reduction to correct the deformity.

Excellent roentgenographic reproductions are included to illustrate the results. These include the prevention of further slipping, acceleration of fusion of the epiphysis, and preservation of a relatively normal anatomy of the hip. Treatment of the slipping while it is minimal permits a simpler operative procedure with an excellent prognosis. It obviates further slipping, eliminates more extensive surgery, and leads to more normal hips.

KENETH H. SPONSEL, M.D.

Treatment of the Necrotic Head of the Femur in Adults DALLAS B. PHEMISTER, *J. Bone Surg.*, 1949, 31-A, 55

Cases in which there was necrosis of the head of the femur are presented in detail. One case was associated with an ununited fracture of the neck. The second case was associated with an ununited fracture at the junction of the head and neck. The patients were treated by drilling two holes across the neck and upper portion of the head of the femur. A rectangular tibial bone graft was inserted into each hole. These fractures united promptly and the upper portion of the head was rapidly invaded and replaced by new bone. There was little roentgenographic evidence of degenerative arthritis 7½ years after operation. A similar result is anticipated in the second case in which a period of 12½ months has elapsed since operation.

In a third case of ununited fracture and death of the head of 2 years' duration, one graft was inserted across the fracture line deep into the head, while the upper graft was inserted only to the margin of the upper portion of the head. Beginning 16 months after operation, the upper portion of the head, which had not been drilled and supported by a graft, underwent collapse and absorption with a poor result.

It is believed that the method here suggested holds promise in cases similar to those presented.

RICHARD J. BENNETT, JR., M.D.

Intracapsular Fractures of the Femur Treated with a Combined Smith-Petersen Nail and Fibular Graft JAMES PATRICK, *J. Bone Surg.*, 1949, 31-A, 67

The technique of fixation in intracapsular fractures in conjunction with the use of fibular grafts and the Smith-Petersen nail is explained in detail.

It is believed that the addition of a fibular graft lengthens the operation time only a few minutes. Sixty-three cases are presented in table form showing the important items of treatment. In 87 per cent of the cases bony union occurred, and in 9 per cent of these there was also aseptic necrosis. The real end result can be judged only after a follow-up study of many years. The number of cases in this series and the length of time involved is too limited. It is suggested that nonweight-bearing does not prevent necrosis. It is also suggested that weight bearing should be avoided for the first 3 months.

The results presented in this article seem to justify the combined use of the Smith-Petersen nail and fibular grafts.

RICHARD J. BENNETT, JR., M.D.

Follow-Up Results of Fractures of the Femoral Shaft in Children—Early and Late Infancy (Résultats éloignés des fractures de la diaphyse fémorale chez l'enfant) N. OECONOMOS, *Rev. orthop.*, Par., 1948, 34, 375

This report is based on 118 patients from the age of 1 to 6 years seen at the St. Louis and Bretonneau Hospital between the years 1939 and 1946. In no case was open reduction necessary. In 70 cases trac-

tion was employed. In 12 cases traction was used for from 30 to 40 hours. In 11 cases reduction was done on the fracture table, in 7 cases traction was applied for from 8 to 10 hours, followed by immobilization in a cast.

Although reduction was not satisfactory in many cases there was no functional impairment. Eventually every deformity disappeared. Shortening was also overcome by compensatory growth. Occasionally the affected limb would grow longer than the unaffected leg. It was therefore to the advantage of the patient to shorten the extremity at the time of reduction to allow for future increased growth which was observed in the majority of cases.

GEORGE I. REISS, M.D.

Arthrodesis of the Ankle Joint W. E. GALLIE, J. *Bone Surg.*, 1948, 30-B 619

Previously, ankle arthrodesis had required wide incision into the joint and the removal of cartilage from the tibia, fibula, and astragalus. This resulted in a poor fit and difficulty in holding the desired position while the cast was being applied. It also gave a thick, ugly appearance which is objectionable. The author's operation overcomes these objections. His technique is as follows: two short, vertical incisions, one in front of each malleolus, are made. The ankle joint is opened and the articular surfaces are exposed. A wide, thin osteotome is then applied to the lower end of the tibia and astragalus by which to cut a deep mortice about $1\frac{1}{2}$ inches long and $\frac{1}{4}$ of an inch wide, the upper half of which involves the lower end of the tibia and the lower half, the articular surfaces of the astragalus and the malleoli. These mortices should be cleanly cut with exactly parallel walls at least 1 inch deep. A bone fragment 3 inches by 1 inch is then cut from the tibia and divided into two parts, each of which is hammered firmly into a mortice. This results in a firm "ankylosis" from the time of surgery. The operation is not complicated and can be accomplished in less than 30 minutes.

The present study is based on 25 operations. All patients obtained painless, bony fusion. Postoperative care consists in leaving the original postoperative cast on for 3 months, following which a walking cast is worn for another month. Patients return to work in from 6 to 7 months.

Modifications of the technique may be required if there is varus or valgus deformity to be overcome. Occasionally osteotomy of the fibula, or removal of a portion of the edge of a tilted astragalus is necessary. In all cases, however, the author relies on the grafts alone for the fusion.

Röntgenograms of gross sections demonstrate the bony fusion obtained. NEWTON C. MEAD, M.D.

ORTHOPEDICS IN GENERAL

A Discussion of Tendon Repair H. MINOR NICHOLS *Ann Surg.*, 1949, 129 223

The author in clear-cut fashion discusses the reasons for common failures experienced in the suture

and repair of flexor tendons according to various levels of involvement.

The poorest results in repair are experienced at the level of the heads of the metacarpal bones and at the bases of the fingers.

In the palm the juncture may be protected from adhesions by using the lumbrical muscles.

At the distal phalanges only slight motion is required so the conditions are more favorable.

Various methods have been employed by modern surgeons. Bunnell recommends slitting the tendon sheath. Koch, Mason, and Allen excise a window in the sheath. Many surgeons who have given up primary repair, advise secondary surgery of the tendons.

Cutler's method of advancing the proximal stump and suturing it as closely as possible to the insertion of the distal stump has been used successfully by the author in 15 cases. Favorable clinical experience is supported by animal experimentation. His work has been rewarded with excellent results and his conclusions appear entirely logical and correct.

1. Gelatin sponge may be placed around a sound tendon without danger and apparently allows earlier free tendon motion.

2. When used about a tendon juncture the sponge causes excessive fibrosis and prolonged fixation of the tendon.

3. Tendon grafts are apparently autolyzed when surrounded by gelatin sponge.

KENNETH E. SHERMAN, M.D.

Quantitative Parathyroidectomy in Orthopedic (Parathyroidectomie quantitative et chirurgie orthopédique) M. SALMON *Rev. orthop.*, Par., 1941, 34 303

Orthopedic surgeons very often observe ankylosis of a joint in which arthroplasty was performed. This complication may be prevented by quantitative parathyroidectomy.

The difficulty of this procedure is based on the fact that (1) the actual amount of parathyroid parenchyma is unknown, and (2) this parenchyma cannot be differentiated from the embryonic islands.

The author presents 2 cases, one in which 80 mgm of parathyroid parenchyma were removed, and one in which 73 mgm were excised. In both cases arthroplasty of the hips was performed and no ankylosis was seen 18 months postoperatively.

The author does not reach any definite conclusion; but is desirous of stimulating further investigation along these lines.

GEORGE I. REISS, M.D.

Congenital Elephantiasis A. W. FARMER, J. *Bone Surg.*, 1948, 30-B 606

Congenital anomalous bands of the extremities are variable in position, depth, and in the completeness of their encirclement. They represent one of a group of abnormalities which are often present in the same individual. Cases associated with gross lymphedema are rare. The treatment of the condition is presented in this article.

A male child, 4 months of age, was admitted to the hospital with multiple congenital anomalies of the hands and feet. There was no history of deformity in the child's ancestors. The left foot presented a tight constricting band which wholly encompassed the limb above the malleoli. Below this encirclement was a tremendous enlargement. The skin was shiny and tight, and it had a transparent, waxy appearance. The tissues were firm. There was no pitting on pressure. After digital compression there was immediate return to the original shape. Radiographs showed very great soft tissue thickening, but there was no abnormality of the bones.

The condition was treated by three operative procedures carried out at intervals of approximately 2 weeks. The first 2 operations were similar in nature: first, the anterior half, and then the posterior half, of the constricting band was excised. In each case a strip of tissue, one quarter of an inch wide and half the circumference of the limb, was excised in the line of the band. Transposition of flaps was accomplished by means of a "Z" plastic maneuver from the normal area above, into the abnormal area below, and vice versa. This was performed on so large a scale as to remove the indentation from the whole circumference of the limb. At a third stage operation, skin and subcutaneous tissues were removed from the dorsum of the foot down to the deep fascia. Part of the skin was converted into a free full-thickness graft by ex-

cision of all subcutaneous fibrous tissue. It was then replaced and a pressure dressing was applied. In one area there was some loss of skin which was replaced later by a split-skin graft.

At the original operation, when the incision was first made, clear fluid flowed from the wound as blood might flow from a large vein. Four test tubes were filled with this liquid which, on analysis, showed a serum protein content of 2.2 gm per cent. Laboratory reports showed that only albumin was present. The fluid did not clot even after several hours. Microscopic examination showed no more than a few lymphocytes.

Histological examination of removed tissue showed a great increase in thickness of the epidermis of the skin from the dorsum of the foot. In a section of the deeper tissues, large lymph channels could be seen clearly.

Before operation it was almost impossible to recognize the shape of the toes. Within a few days of the first operation there was remarkable shrinking of tissues. By the time the patient was discharged from the hospital, after the third operative procedure, the foot was almost normal in appearance. Re-examination several months later showed that the cosmetic appearance was still satisfactory and function was excellent. There had been no recurrence of swelling or enlargement of the limb.

Arteriography in Pathologic Stumps The Role of Arterial Circulation in the Genesis of Trophic Disturbances (De l'artériographie dans les moignons pathologiques Du rôle de la circulation artérielle dans la genèse des troubles trophiques) RENÉ LERICHE *Presse méd*, 1949, No 2 23

Arteriography plays an important role for the differentiation of the causes of trophic disturbances in stumps. Poor circulation may be caused either by obliteration or by spasm of the main artery. On the other hand, a too abundant vascularization and circulation may also cause trophic and vasomotor disturbances, and pain.

Lumbar gangliectomy may give relief in many cases
WERNER M. SOLMITZ, M.D.

An Experimental Study on the Use of Dicumarol in Arterial Suture (Sull'uso del dicumarolo nella sutura delle arterie Ricerche sperimentali) FILIPPO BELLANTI *Rass internaz clin ter*, 1948, 28 553

The right femoral arteries of 14 dogs were exposed for a distance of 3 cm. under local anesthesia, and an incision 1 cm. in length was made into the lumen of each, proximal and distal loops of silk being used for temporary hemostasis. The arteries were then repaired with continuous 0000 chromic catgut on an atraumatic needle, the edges of the vessel wall being everted, which decreased the size of the lumen by one-third. Six of the dogs received dicumarol for 4 days prior to operation and during the postoperative period. The drug was given in amounts sufficient to maintain a prothrombin time double that of their previous normal figure. Eight dogs were used as controls and were not given dicumarol. Twenty days after operation the dogs were sacrificed by exsanguination under ether anesthesia and the sutured arteries were examined macroscopically as well as by serial microscopic sections.

It was found that each of the untreated dogs developed a thrombus which obliterated the lumen at the site of the suture line, whereas the lumen was patent in every one of the treated dogs and in only 1 dog were there a few small thrombi.

The author concluded that, in dogs, dicumarol demonstrated its value in maintaining the patency of sutured arteries.
N. CHRISTIAN MEYER, M.D.

Multiple Arterial Emboli 3 Successful Embolectomies in a Case of Bacterial Endocarditis H. WILLIAM SCOTT, JR., and J. MAXWELL WILLIAMS, JR. *Arch Surg*, 1949, 58 28

The optimal treatment of peripheral arterial emboli involving the lower extremities is prompt embolectomy, with local anesthesia, supplemented by lumbar sympathetic block and the use of papaverine and anticoagulants.

The case reported illustrates the value of prompt recognition of the situation in repeated episodes of peripheral embolism, and the desirability of close cooperation between medical and surgical services in utilizing this plan of treatment. Arterial embolism is a true surgical emergency, and a markedly diminished cardiac reserve should not be a deterrent to arterial embolectomy, with local or regional anesthesia.

Lumbar sympathetic block was not performed before the second embolectomy because a spinal anesthetic, accomplishing the same purpose, was given almost immediately. It is of interest to note that during the second and third embolectomies no excessive bleeding was encountered, despite the fact that the patient was fully dicumarolized. All wounds healed by first intention without hematoma or ecchymosis.

Major embolic phenomena occurring during the course of bacterial endocarditis are usually visceral. Large peripheral emboli occluding the major vessels of the extremities apparently have been uncommon. Several observers have noted an increased incidence of embolism since the advent of intensive penicillin therapy of this disease. It is possible that cases of the type reported here will be encountered more frequently in the future.

BENJAMIN GOLDMAN, M.D.

Phlebography and Surgery of True Varicose Veins of the Lower Limb (Phlébographie et chirurgie des varices essentielles du membre inférieur) CL. OLIVIER *Presse méd*, 1949, No 2 36

Although injection of sclerosing substances is satisfactory in many cases, a certain percentage of recurrences is observed even in the hands of the most experienced therapists. Therefore, many surgeons, especially in the Anglo-Saxon countries, perform routine ligation of the saphenous vein after injection of morrhuates or similar substances. This method of treatment gives better results than injection alone, however, even with this method, a certain percentage of failures occur due to short circuits via communicating veins to the deep vessels. Furthermore, if injection treatment precedes the ligation, embolisms or phlebitis may occur in rare instances.

By phlebography, the short circuits can be ascertained and their location visualized. Therefore, phlebography should be done routinely in all cases before the type of treatment is decided upon.

The author recommends ligation not only of the trunk of the saphenous, but the perforant tributaries which communicate with the deep venous network, and which can be localized easily by phlebography. The ligation should precede the injection treatment in order to obviate accidents and to shorten the time of bed rest. This method has been used in 100 cases since 1943 without a single incidence of embolism or

phlebitis. In local anesthesia, the vein is exposed by vertical rather than by horizontal incision close to the femoral vein, and resected to a length of 4 cm. At the same time, all communicating tributaries, previously demonstrated by phlebography, are ligated. The patient is not confined to bed at all and leaves the hospital on the fourth day after surgery. One month later, the sclerosing injections are done. Usually, much fewer injections are necessary than in the preoperative injection method.

Finally, the author stresses the beneficial effect of this method of treatment on the healing of varicose ulcers.

WERNER M. SOLMITZ, M.D.

Treatment of Varicosities of the Lower Extremities
(Tratamento actual das varizes dos membros inferiores) JOSÉ DE BORJA ARAÚJO *Gaz. méd. Portuguesa*, 1948, 1: 644

Four methods of treatment of varicosities of the lower extremities may be distinguished, as follows:
1 Prophylaxis, chiefly applicable to pregnant women who should be instructed to do bending and stretching exercises of the legs several times a day, and to assume a reclining position with the legs elevated in the middle of the day.

2 Conservative treatment consisting of the application of elastic bandages and elevation of the lower extremities, and employable when there are contraindications to an active therapy, e.g., senility, debilitating diseases, impairment of arterial circulation, pelvic tumors or other obstacles to the venous reflux, pregnancy, and phlebitis of the deep veins.

3 Employment of sclerosing substances alone or combined with operative procedures. The author reports recurrences in 60 per cent of cases in which injections alone had been given.

4 Operative methods, namely, single or multiple ligations, with or without concomitant injections of sclerosing solutions. The vena saphena magna is exposed at its junction with the femoral vein through a longitudinal incision, the vein and its tributaries are ligated, the lesser or external saphenous vein is exposed in the popliteal region. Five cubic centimeters of sodium morrhuate are injected into the distal portion of the transected vein.

In patients with bilateral varicosities, the author prefers to perform the operation in two stages, allowing a period of 7 days to elapse between them.

JOSEPH K. NARAT, M.D.

Further Consideration of the Surgical Management of Chronic Varicose Ulcers N. OWENS and H. BETHEA *Plast. Reconstr. Surg.*, 1948, 3: 633

The authors present a brief history of varicose ulcers and their treatment. Chronic varicose ulcers of the lower extremity are more commonly observed than any other type, they represent about 90 per cent of all chronic ulcers of the leg. Heredity is an important factor in about 65 per cent of all patients suffering from varicose veins or chronic ulcers. These ulcers frequently occupy the area above the medial malleolus and occur on the left leg more often than

on the right. The incidence of syphilis in chronic ulcers of the lower extremities is discussed. A small percentage of chronic ulcers of the lower extremity will be found to arise as the result of sickle cell anemia. Both of these conditions should be ruled out before a positive diagnosis of chronic varicose ulcer is considered established.

An extended discussion of the pathologic characteristics of these cases is presented. One of the factors in the development of a chronic leg ulcer is that of venous stasis. Associated with this is a progressive anoxemia and local acidosis which develops as the result of stagnation of the metabolic processes in the skin and subcutaneous tissue. Slight trauma to the tissue undergoing such alterations provides an entrance to bacteria that leads to early ulceration and may act as a focus for the development of chronic leg ulcer. Because of the lowered resistance of local tissue, infection is difficult to combat. Progressive infection means further interference with lymph drainage, subsequent proliferation of scar, and increased diminution of local blood supply.

The author observes that probably no surgical condition has been subjected to a greater variety of treatments than chronic varicose ulcers of the lower extremity. During the initial, acute stage of the development of varicose ulcers, approximately 50 per cent of these ulcers could be cured by relatively simple methods. The administration of penicillin and the sulfonamides, in association with venoligation and injection, physiologic rest, elevation of the extremity for adequate drainage, and the application of moist, saline pressure dressings should insure a satisfactory cure in the vast majority of these early cases. A satisfactory cure will require that treatment be directed to chronic varicose ulcers complicated by varying amounts of infection, marked diminution in the vascular supply, sufficient disturbance in the local lymph drainage to produce chronic lymphedema, and a massive amount of scar. Obviously, that treatment must offer an adequate blood supply to the part and correct the disturbance in lymph drainage of the local area if the other pathologic states are to be improved. From a study of the regional anatomy, it appears that the correction of these defects will entail complete excision of all offending scar, together with complete excision of an equal area of deep fascia because the deep fascia completely invests the musculature of the lower leg, and separates the blood supply into the superficial and deep circulation.

In all of the cases reported in the present article, half-thickness grafts were applied immediately following the excision of scar and deep fascia. All grafts have remained entirely stable and there has been no disability due to adherence of the grafts to the muscles, tendons, or bones. There have been no breakdowns in the grafts that have not been associated directly with trauma and which have not healed spontaneously. The postoperative care of these patients is a very important factor in the success of the procedure. After the application of the graft,

single layer of surgical rayon is applied over the graft, followed by the application of the usual type of pressure dressing held fixed by a No 8 Ace bandage. The foot is splinted to produce complete immobilization. The patient is kept in bed for 4 or 5 days and the dressing is then changed with reapplication of the splint. When the graft has become firmly attached and circulation is insured, the patient is supervised in a series of vascular exercises. These exercises are described in detail. Eight cases are presented in detail together with photographs illustrating the procedures for each of the ulcers.

HERBERT F. THURSTON, M.D.

The Question of Gangrene Following Popliteal Injury (Ueber die Frage der Gangraen nach Popliteaverletzung) BÉLA GOMBKÖTÖ *Helvet chir acta*, 1948, 15: 454

The author presents his views concerning the high percentage of cases of gangrene of the lower extremity following injury to the popliteal artery. He considers the older points of view concerning well developed collaterals, good heart function, and complete adaptability of the circulatory system, as well as the opposing points of view that the number and caliber of collateral vessels at the knee are or are not adequate. He believes that the results of animal experiments throw little light on the subject, and that the occurrence of the condition may be explained by phylogenetic circumstances.

The collateral circulations at the shoulder and hip are not analogous to that at the knee, since at the knee there are hardly any arteries which contribute to the collateral network that originate higher up and are not involved in the injury. The connections of the branches proceeding from the popliteal artery itself upwards are maintained by the popliteal artery alone. In the case of early ligation of the popliteal artery, collateral circulation does not develop because the capacity of the available collaterals is poor, due to fall in blood pressure, pressure of the hematoma, and also because of the fact that the major part of the collateral circulation has been damaged along with the popliteal artery and is dependent on the popliteal artery. The results of ligation of the cubital artery at the elbow and the popliteal artery at the knee are different because the circulation at the corresponding regions is dissimilar. The collaterals at the elbow originate higher and terminate lower into the chief branches than those at the

knee. At the knee the popliteal artery and the collateral branches are confined to a smaller space than are the vessels at the elbow.

LYMPH GLANDS AND LYMPATHIC VESSELS

Notes on the Anatomy and Physiology of the Thoracic Duct and on the Treatment of Injuries to It LARS HOLMBERG *Acta chir scand*, 1948, 97: 215

Four cases of injury to the thoracic duct are reported. Excision of the left cervical metastatic nodes, scalenotomy plus division of the cervical sympathetic trunk, a Peet sympathectomy, and a possible traumatic rupture accounted for the injuries. In 2 of the cases reoperation with ligation of the duct in one and tamponade in the other was required. In the third case the injury was discovered at operation and the ends of the duct were sutured. The injury healed spontaneously in the fourth case.

A summary of the literature with regard to the anatomy and physiology of the thoracic duct and the treatment of its injuries is presented. The consequence of either an internal or external thoracic duct fistula is usually a rapid loss of protein, fluid, salts, and fat. Inanition quickly supervenes if the patient is left without effective treatment. Blood and plasma transfusions, a rich diet, and protein substitutes are recommended. Fat should be reduced to a minimum in the diet and it is suggested that the administration of atropin may lessen the flow of chyle. The chief finding of internal affections of the thoracic duct is said to be chylothorax, for which thoracenteses may be employed.

Ligation is recommended for the injury in the cervical portion of the duct with tamponade reserved for those cases in which it fails. An expectant attitude is warranted in those injuries which involve the intrathoracic portion, for the operative correction of the defect is considerably more difficult. Should the defect fail to heal spontaneously, ligation of both the central and peripheral ends must be made. External drainage of these injuries may be resorted to only as a palliative procedure to prevent the formation of chylothorax and its complications. As a result of modern fluid therapy and the progress of cervical and thoracic surgery the prognosis may now be judged to be relatively good.

ALLAN D. CALLOW, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE, POSTOPERATIVE TREATMENT

The Use as Controls of Various Hematologic Values and in Particular the Plasma Protein Level after Surgical Intervention (Sull'utilità del controllo di alcuni valori ematologici ed in particolare del tasso delle proteine plasmatiche dopo interventi chirurgici) CORRADO CONFALONIERI *Ann ostet gin*, 1948, 70 601

The author reviews the literature on the value of protein therapy in surgery. He then reports on studies made on 20 patients. Plasma protein, hematocrit, hemoglobin, and red cell determinations were made preoperatively, immediately following surgery, and during convalescence. All the data are given for each case.

Hypoproteinemia was found in 16.6 per cent of the cases. It was noted that fever was more common with hypoproteinemia, but it was also noted that this was true in the patients subjected to major surgery. Edema was not encountered, and it was believed that this was accounted for because no values below 4.5 per cent (the absolute limit of edema of Efskind) were found. One wound with infection and another with poor healing were both associated with low protein values.

The author believes that one cannot estimate blood loss or protein values without laboratory studies. He uses the Phillips copper sulfate gravimetric method for determining the plasma protein values because he believes that it is more practical than the more precise methods. The use of amino acids is recommended when the plasma protein values are low and their administration should be controlled by plasma protein determinations.

LUCIAN J. FRONDUTI, M.D.

ANTISEPTIC SURGERY, TREATMENT OF WOUNDS AND INFECTIONS

The Nature of the Shift of Plasma Protein to the Extravascular Space Following Thermal Trauma OLIVER COPE, JOHN B. GRAHAM, FRANCIS D. MOORE, and MARGARET R. BALL. *Ann Surg*, 1948, 128 1041

Discussion of the circulatory disorder of the burned patient and of the need for fluid is inadequate if it does not include a consideration of the abnormal distribution of the plasma proteins which occurs within the body as a direct result of the injury. Colloid osmotic pressure is exerted by the plasma proteins in differential concentrations on either side of the semipermeable capillary membrane which portions water between the plasma and the interstitial space. The sudden increase in permeability of the capillary wall caused by the burn destroys the osmotic pressure of the plasma in the area of injury and permits the collection of edema in the wound.

Two current misconceptions regarding the distribution of plasma proteins are (1) that the proteins of plasma circulate only within the blood stream, and (2) that the remaining circulating plasma has a lowered protein concentration.

The disordered distribution of protein as a result of a burn has been approached experimentally by collecting lymph flowing from the burned foot of the dog. There is an increased flow of lymph following the burn and a significant one in lymph protein. This indicates the permeability of the damaged capillary membrane to protein. The degree of capillary damage depends to an extent upon the intensity of the burn. However, no matter how severe the burn, the protein concentration of the lymph is never as high as that of the plasma. There is only a portion of the plasma protein that passes with the water into the lymphatics. The unaccounted for fraction is not lodged in the wound, as indicated by the observation that fluids removed by needle from the wound have protein concentrations slightly lower than that of the lymph. There is only one place for the unaccounted for protein fraction to be and that is still in the blood stream.

This assumption was proved by the findings of an increased protein concentration in the plasma of dogs after burning. The dilution of protein succeeding the initially increased concentration indicates withdrawal of fluid from the unburned tissues into the blood stream.

It was proved experimentally that the initially more concentrated plasma does not take back water from the wound. The lymphatic trunks of the hind feet, the neck, and the thoracic duct of the dog were cannulated and a control flow of lymph was observed. The feet were then burned and when the typical curve of increasing lymph flow from the feet and rising serum protein concentration and hematocrit were established the animal was given hypertonic albumin intravenously. The hematocrit fell promptly, and this represented an increase of plasma volume due to absorption of fluid from the tissues. This fluid came virtually entirely from the unburned tissues and not from the burn wounds as indicated by cessation of the flow of lymph from the cervical trunk and a drop in the thoracic duct pressure while the increased flow from the burned feet continued. The cessation of flow of lymph from the cervical region persisted and indicated severe dehydration of this unburned region of the body. This suggests that the mechanism for the reabsorption of water locally is also damaged by a burn, the only mechanism for return of fluid from the wound remaining intact being the lymphatic system.

The osmotic influence of the increased concentration of protein found in the circulating plasma, immediately after injury, upon the water concentration of the unburned tissues depends in part upon the

albumin-globulin ratio The lower the ratio the less dehydrating it should be This was proved experimentally by using radioactive diazo dyes and by chemical analysis of the proteins in both the plasma and lymph of dogs As a result of the burn the capillary wall becomes wholly permeable to albumin but not to the globulins This fall of the albumin-globulin ratio encountered immediately after injury should offset or reduce the rise in osmotic tension indicated by the increase in concentration of the total proteins

Tests for abnormal proteins were made but none was found

Clinical observations on burned patients were made, comparing the protein content of the initial blebs at varying time intervals with that of the blood plasma This data on the human patients gave comparable results with the same implications as those on the dog HARVEY S ALLEN, M D

Antibiotic Therapy for Cutaneous Anthrax Report of 5 Cases W A REILLY and C R BEESON *Arch Int M*, 1948, 82 529

The purpose of this article is to outline the favorable results of treating cutaneous anthrax with penicillin and sulfadiazine and with streptomycin

It is claimed that the incidence of anthrax is rising in the United States

For many years there has been a greater incidence of human anthrax in the United States in certain areas, i e, the Atlantic seaboard, in which infected hides from foreign countries (Arabia and Egypt) were processed

The patients in cases 1, 2, 3, and 4 were given 300,000 units of penicillin and sulfadiazine daily for 5 days Improvement started within 24 hours and continued thereafter

The improvement in all 4 was quick in onset and progressively more notable daily Some evidence of the "tissue damaging factor" of the *Bacillus anthracis* was detected, but it was only slight This damage, probably due to the toxin, continues to operate for a short time after the organisms have been killed by the penicillin

In case 5 the dosage of streptomycin was in keeping with the normal amount recommended for its proper usage The patient's toxicity and the malignant appearance of the lesions were decreased to a great extent within the first 24 hours, the fever disappeared after 36 hours, and axillary lymphadenopathy was barely palpable (the areas being no longer tender) by the sixth day of treatment with streptomycin The renal lesion slowly improved and was not aggravated It is possible that the dosage of the drug and the duration of its administration could have been decreased

A choice between penicillin and streptomycin for therapy in human beings would at present probably favor penicillin for it has more effectively suppressed the cultural growth of anthrax, it is more widely distributed, and it costs less since only from 100,000 to 200,000 units daily for from 5 to 7 days are required

A sensitivity test with the two antibiotics is very desirable when there is doubt, as, for instance, when a patient has cutaneous anthrax and septicemia

GEORGE W RICHARDSON, M D

The Use of Penicillin in Open Injuries of the Hand and Fingers (*L'emploi de la pénicilline dans les traumatismes ouverts de la main et des doigts*) M BELENGER *Acta chir belg*, 1948, No 8 490

The author believes that, in the era of antibiotic therapy, the indications for mutilating operations of the hand and fingers should be completely revised

Up to recent times, the fear of infections caused most surgeons to recommend finger amputations or other mutilating interventions in the majority of open injuries with fracture The author suggests a much more conservative proceeding Only total interruption of the circulation or complete crushing of all the soft tissues warrants ablation Under penicillin therapy, from 30,000 to 100,000 units every 3 hours for 2 to 3 days, not one infection occurred in a series of 148 complicated fractures although in part of the cases the phalangeal articulations were open and exposed Suture of the opened joints and severed tendons, and skin grafts when necessary gave excellent functional results which would not have been possible before the penicillin era

Healing of the injuries was considerably accelerated under this therapy The author shows in an interesting table that the average time until return to work was reduced by more than one-third as compared with patients treated without antibiotics

WERNER M SOLMITZ, M D

ANESTHESIA

Anesthesia for Neurosurgery LOUIS L TEPLINSKY, ZIGMORE HARRIS, W H CASSELS, and OSCAR SUGAR *Anesthesiology*, 1949, 10 82

The anesthesia problems involved in neurosurgery are analyzed and a number of requirements are outlined The characteristics of the common anesthetic agents as they pertain to these requirements are discussed

The authors state that ideally, we should find a solution common to all these problems, but practically, this has never been achieved We are forced to compromise and to accept the solution which most nearly meets all the requirements A method of anesthesia in which nitrous oxide is supplemented with dilute pentothal solution by drip, and intubation is facilitated by topical anesthesia has proved satisfactory in a series of 203 cases

MARY FRANCES POE, M D

Anesthetic Management for Surgery Within the Thorax A Report of 309 Cases KATHERINE FISHER, LAWRENCE D LEE, DIRK E STEGEMAN, and ROBERT B YOUNG *Anesthesiology*, 1948, 9 623

The authors present the methods used by one group of anesthesiologists in dealing with the special

problems encountered in the management of anesthesia for major intrathoracic surgery. The operative and postoperative courses have been studied, and a comparison made as to the efficacy of the various agents and the condition of the patient.

The goal of the anesthetist in intrathoracic surgery is to produce satisfactory anesthesia with adequate oxygen for all tissue requirements and to prevent the secretions of the diseased lung from entering the healthy one. The method that has seemed to prove most satisfactory in this series is endotracheal anesthesia with the patient in deep Trendelenburg position. The anesthetic combinations which seem to depress the patient the least with a minimum of untoward effects are pentothal with topical anesthesia, or pentothal and curare for intubation, followed by ether, or ether and curare for maintenance. Certain undesirable results have been observed with cyclopropane.

Strict attention to detail and co operation between the anesthetist and surgeon have been factors in lowering the mortality and the morbidity.

Myanesin As a Muscle Relaxant HAROLD R. GRIF-FITH, C. R. STEPHEN, WILLIAM G. CULLEN, and WESLEY BOURNE *Anesthesiology*, 1940, 10 61

The muscle relaxing properties of myanesin, one of the substituted ethers of glycerol, have been reviewed from clinical and laboratory experience, and compared with curare. The present study was motivated by the report of Mallinson who concluded, from clinical experience in 112 patients, that myanesin appeared to have well marked advantages over curare, such as a wider margin of safety, abdominal relaxation in the conscious patient without distressing intercostal paralysis, and with full abdominal muscle relaxation.

In this series myanesin was administered to 120 anesthetized patients, 75 conscious patients, and to 25 cats and rabbits. The results were compared with more than 2,000 personally observed administrations of curare in anesthesia, either as intocostarin or one of the preparations of d-tubocurarine chloride. Myanesin was used in the same kind of cases and under the same conditions as curare was used. Cyclopropane was the most commonly used anesthetic agent. It was found that myanesin was effective as a muscle relaxant provided enough of it was used, but its relaxing effect was less predictable in any case. The average dose was 8.7 c.c. With myanesin, the duration of relaxation was no longer than that obtained with curare, and respiratory depression was observed as occasionally as with curare. The relaxing effect of 10 c.c. of myanesin appeared to be approximately equal to that of 3 c.c. (60 units) of intocostarin.

Observations of the conscious patient given 20 mgm. of myanesin per kilogram of body weight at the rate of 1 to 2 c.c. per minute demonstrated that there were no measurable effects on nerve and muscle action potentials upon transmission at the neuro-

muscular junction, on induction along the sciatic nerve, or on synaptic transmission of impulses through the spinal cord. This led to the opinion that the site of action of the drug was central rather than peripheral. None of the conscious patients showed any loss in voluntary muscle power as measured by the dynamometer.

The disadvantages to the use of myanesin are (1) occasional local irritation set up in the vein at or above the site of injection, and (2) the occurrence of hemoglobinuria associated with albuminuria. These complicating factors are sufficiently serious to indicate that myanesin in its present form is not a satisfactory substitute for curare in clinical anesthesia. Through its central action the drug may have some useful place in the treatment of certain neurologic diseases, and its further study in this field should be encouraged.

MARY KARR, M D

Intravenous Demerol-Scopolamine Amnesia During Labor JOHN M. BROWN, PERRY P. VOLPITTO, and RICHARD TORPIN *Anesthesiology*, 1940 10 15

A method is described in which demerol hydrochloride and scopolamine hydrochloride was utilized during parturition.

The first administration of the drug is at the onset of true labor, that is, when labor pains are of 40 seconds duration, and when they occur at regular intervals of 5 minutes or less. At this point a solution containing 10 mgm. of demerol and 1/1000 grain of scopolamine per cubic centimeter is injected intravenously at the rate of 1 c.c. per minute until the patient begins to talk incoherently, shows signs of falling asleep between pains, and exhibits only a slight amount of restlessness with each pain. Usually this initial dose is from 8 to 10 c.c. of the solution in those patients who had received no previous drugs. The second intravenous injection (an average of 3 to 5 c.c. of the solution) is required in from 2 to 3 hours after the first. This is usually sufficient for multiparas, however, primiparas require a third administration in from 3 to 5 hours after the second. The criteria for a repeat dosage are undue excitement with each pain, restlessness, alertness and coherence, and the lapse of time from the last injection of the drug.

All episiotomies are performed under local anesthesia and repaired under cyclopropane anesthesia. This technique was employed in 250 obstetrical patients over a period of 1 year, and 100 unselected case histories were studied in detail, with information on method of delivery, progress of labor, infant mortality and morbidity, state of the newborn, amnesia during labor, and analgesia during labor.

The primary effect of the combination of agents used was the production of adequate amnesia in a high percentage of the patients studied (excellent in 53.3 per cent and good in 32.6 per cent). Demerol, as employed in these cases, produces a sufficient degree of analgesia to reduce the restlessness of the mother during labor, but not a sufficient amount of analgesia to reduce pain entirely.

The incidence of apnea neonatorum was low, this condition occurred in only 10 patients, 6 of whom required resuscitation. The previous or simultaneous administration of barbiturates or morphine with demerol resulted in a greater incidence of apnea in the newborn.

The administration of these drugs is justified because of the amnesic action of scopolamine and the analgesic action of demerol. The intravenous route of administration of these drugs produced side effects of a minor nature. No spasmolytic effect of demerol was observed upon the uterus. The potentiation of barbiturate medullary depression by demerol was noted.

MARY KARP, M D

A Study of Pentothal Sodium Anesthesia and a Critical Investigation of the Use of Succinate as an Antidote JOHN H TUCCI, MARY A B BRAZIER, HENRY H W MILES, and JACOB E FINESINGER. *Anesthesiology*, 1949, 10 25

Some of the biochemical aspects of the oxidative theory of anesthesia are presented and discussed. On the basis of succinate oxidation being unaffected by barbiturate anesthesia, the authors postulate that disodium succinate might be expected to act as an antidote to sodium pentothal anesthesia.

Electroencephalogram records were used as the objective record in the cases studied. Both healthy males and psychiatric patients were studied; the psychiatric diagnoses were all in the psychoneurotic classifications. Pentothal sodium anesthesia was induced and a classification of the stages and planes of anesthesia was made on the basis of clinical observation correlated with electroencephalographic records.

Disodium succinate was administered intravenously before, during, and at the completion of anesthesia, and controls were run with other sodium salts instead of succinate. The electroencephalographic effects of the succinate administration were variable, as were the clinical findings. Some patients awakened more rapidly following the succinate, but others were essentially unchanged.

The authors conclude that a definitive decision as to the value of succinate would be unjustifiable at this time.

Several variables, such as tolerance to pentothal sodium, are suggested as reasons for the need of caution in assessing the antidotal effects of disodium succinate.

R GIBSON PARRISH, M D

Tachycardia in Children During Anesthesia KATHERINE JACKSON *Anesthesiology*, 1948, 9 573

The present study was undertaken to determine the effect of four factors upon the average maintenance pulse rate during anesthesia, namely: preanesthetic apprehension, premedication with nembutal, the agent used, and the technique of administration. In 108 children, the pulse rate was recorded at frequent intervals during the period of anesthesia. Averages of these individual readings were used to compute a general average maintenance pulse rate

for the entire group. Repeated pulse readings, on the wards, of the same group of children provided a control.

The average maintenance pulse rate was 10 to 14 per cent higher in the apprehensive group than in the group that showed no fear. Nembutal premedication seemed to have a physiologic sedative effect independent of its psychic sedation since in the non-apprehensive children, those who had been given nembutal had 10 per cent lower pulse rates than those who had not had nembutal. The lowering of the pulse rate was particularly noticeable in the younger children.

For the purpose of maintaining a more physiologic pulse rate, cyclopropane seemed to be a better anesthetic agent than ether. The technique of administration has little effect on the average pulse rate in children during anesthesia. When ether must be administered, the quiet child is much more likely to have a reasonably physiologic pulse rate than is the apprehensive child.

SURGICAL INSTRUMENTS AND APPARATUS

Blood Determination and Estimation of Blood Loss During Surgical Operations NORRIS E LENAHAAN, THEODORE A SPITZ, and DEFOREST W METCALF *Arch Surg*, 1948, 57 435

The gravimetric method was used to estimate the blood loss from a variety of surgical procedures. During the course of an operation the curve of the blood loss and the curve of blood gained by transfusion could serve as a guide to the volume of necessary replacement.

In the present article the blood loss incurred in 270 surgical operations was reported. The average

TABLE 1 — DATA ON BLOOD LOSS

Operations	Number of cases	Blood loss cc.		
		Minimum	Maximum	Average
Hernia	20	25	75	40
Appendectomy	20	25	50	35
Hemorrhoidectomy	20	25	150	55
Salpingectomy	25	80	225	150
Hysterectomy	25	155	375	300
Thyroidectomy	10	75	200	125
Biliary	10	75	525	300
Gastric resections	12	320	780	503
Intestinal resections	10	510	1 425	760
Abdominal perineal resections	10	415	2,420	1 080
Vagotomy	10	165	690	423
Suprapubic prostatectomy	10	265	1 235	551
Transurethral resections	15	172	855	563
Nephrectomy	10	285	845	478

loss of blood in 12 gastric resections was 503 ml. It was emphasized that in the latter operation there was a tendency to overinfuse the patient with blood unless the actual loss was measured.

BENJAMIN G. P. SHAFIROFF, M.D.

Concept and New Techniques of the Dermoepidermal Graft (Conception et technique nouvelles de la greffe dermo-épidermique) F. LAGROT and R. FAVRE. *Rev. chir., Par.*, 1948, 67: 332.

The authors present their concept and technique of skin grafting after 3 years of extensive experience with skin lesions requiring cutaneous grafts. They emphasize the importance of early grafting before extensive cicatrization has occurred. Third degree burns were grafted by the eighth day, after careful preparation with chemotherapy, débridement, and local application of a solution of salt, glycerin, and acetic acid which aided in the separation of the eschar. Traumatic avulsions were immediately débrided and grafted with excellent results. The authors also grafted cutaneous ulcerations including extensive cutaneous anthrax, and many postoperative wounds doomed, by their extent, to heal by second intention.

Their grafts were of the split-thickness variety, usually obtained from the anteromedial aspect of the thigh by means of an adjustable razor plane. The superficial surface of the graft was spread out on vaseline gauze or tullegras, and cut to the desired size. Excessive skin was refrigerated in glass tubes and remained viable for 20 days.

The authors illustrate their technique of grafting a large cutaneous anthrax. Complete excision of the ulcerated area is carried out. Hemostasis is accomplished by electrocoagulation and adrenalin compresses. Several uncut wire sutures are placed around the periphery of the lesion. The graft is treated with a "glue" of plasma and prothrombin, and is placed in position. The peripherally placed wire sutures are then tied over several layers of gauze, thus holding and compressing the graft in place.

Following operation, the grafted areas are immobilized as completely as possible for a period of 7 to 10 days. Extremities are elevated and enclosed in plaster with windows cut over the grafted areas. Ice bags are applied to these areas for 8 days after the operation, in order to prevent necrosis of the graft. Chemotherapy is administered during the entire preoperative and postoperative period. The first dressings are done on the seventh to tenth days and the preserved "refrigerated" grafts are applied to any denuded zones.

The authors used homografts in several cases without success. They noted that grafting with the same foreign skin two different times resulted in more rapid destruction of the graft the second time. This phenomenon, they believed, was of an anaphylactic type, and they suggest the possibility of desensitizing the recipient with a skin extract of the donor prior to grafting.

According to the authors' statistics, they obtained 92 per cent successful "takes" in 100 cases by their method of skin grafting. JOHN H. FLANN, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

New Applications of the Principles of Kymography
(Nouvelles applications des principes de la chymographie) LOPO DE CARVALHO *Bruxelles méd*, 1948, 28 2709

The author describes a method by which the circulation time is accurately measured by the injection of thorotrast into the vein of the arm. For this purpose he and his coworkers revived the old kymograph with a transverse split. A film moving downward at known speed gives the kymograms of the superior vena cava, aorta, main branches of the pulmonary artery, and pulmonary veins. The kymograms appear on the film at different times depending upon the lung circulation time. They are measured by the known speed of the film. On varying the position of the split, the time of the right and left heart circulation and that of the pulmonary tree can be measured. This method can be applied to other organs, the brain, and the limbs.

In the second part of the article the author describes a procedure for determining the mobility of the wall of a cavity in the lung. For this purpose he devised a kymograph with two crossed splits moving clockwise and describing a 90 degree angle. The center of the cavity must coincide with the point at which the two splits cross. Some practical examples of the usefulness of this apparatus are given.

MARC K. P. STU, M.D.

Visualization of the Cavum Tympani and the Auditory Canal with Opaque Medium Experiments on Dogs (Visualizzazione con mezzi di contrasto opachi del cavo del timpano e della tuba auditiva. Prime esperienze sui cani) MARIO FACCINI *Radiol med*, Milano, 1948, 34 842

An opaque medium, namely, ioduron (30 per cent iodized oil), was injected by the author into the pharyngeal orifice of the eustachian tube in dogs. The reaction of the mucosa of the cavum tympani and the rate of elimination of the opaque medium were studied.

The author suggests the employment of this method in man, especially in skull fractures involving the cavum tympani.

The histologic examination of the mucosa from 4 to 8 weeks after the injection failed to reveal any sign of sclerosis or inflammation.

JOSEPH K. NARAT, M.D.

Peripheral Vascular Disease in the Lungs ROBERT P. BARDEN and DAVID A. COOPER *Am J Roentg*, 1949, 61 17

Conditions producing changes in the peripheral vascular system may be demonstrable in chest roentgenograms. They are congestion following heart disease, intrinsic vascular obstruction, in-

trinsic disease of a blood vessel, obliteration of vessels by adjacent pulmonary disease (tuberculosis, carcinoma, abscess), and hypersensitivity states and toxins causing increased permeability (collagen diseases).

Illustrative cases are reported depicting the various vascular lesions of the lungs which may be of differential diagnostic value in problem cases.

MAURICE D. SACHS, M.D.

Stratigraphy in 1947 and in 1930, from the Initiation to the Termination of Thoracoplasty (La stratigrafia 1947 e la stratigrafia 1930 nell'indagine degli esiti di interventi di toracoplastica) ALESSANDRO PIAZZA *Radiol med*, Milano, 1948, 34 753

The value of combination of the customary roentgenographic technique with stratigraphy is illustrated by the author in 5 cases. The customary stratigraphic examination was done in 1930 in all 5 patients, and in 1947 transverse axial stratigraphy was also employed in 3 of the patients. Such combined examinations are of particularly great value in the determination of skeletal deformities and for study of the evolution of cavities after thoracoplastic operations.

The three-dimensional images are of especially great value for the study of secondary thoracopulmonary alterations, such as deviation of the spine or mediastinum, following surgical intervention.

JOSEPH K. NARAT, M.D.

The Roentgenologic Symptoms of Esophageal and Gastric Injuries Resulting from Caustic Poisons (Roentgensymptome der Speiseröhren und Magenverletzungen durch ätzende Gifte) IVÁN RODE. *Acta radiol*, Stockh., 1948, 30 105

The material for this report consists of 111 cases of caustic poisonings. Of these, 79 were poisonings with lye, 29 with acids, and 3 with other caustic substances. Of the patients poisoned with lye, 78 were females and 1 was a male. The average age of the women was 22 years, the youngest being 14 and the oldest 59. The man's age was 25 years. The alkali used was always sodium hydroxide. All of the patients poisoned with acids were women. Of these, the average age was 24 years, the youngest being 17 and the oldest 47. The acid used in 24 instances was hydrochloric acid, in 2, sulphuric acid, in 2, oxalic acid, and in 1, formic acid. Because of the similarity of effect with acid poisonings there were also classed with this latter group a case of potassium permanganate poisoning, a case of zinc chloride poisoning, and a case of formalin poisoning.

In 18 of the patients poisoned with alkali and in 9 poisoned with acid no pathologic changes in the esophagus or stomach could be found. In the remainder, more or less outspoken alterations could be demonstrated, in the less severe cases only spasmodic

loss of blood in 12 gastric resections was 503 ml. It was emphasized that in the latter operation there was a tendency to overinfuse the patient with blood unless the actual loss was measured.

The Roentgenologic Symptoms of Esophageal and Gastric Injuries Resulting from Caustic Poisons (Roentgensymptome der Speiseröhren und Magenverletzungen durch ätzende Gifte) IVÁN RODÉ *Acta radiol*, Stockh., 1948, 30 105

The material for this report consists of 111 cases of caustic poisonings. Of these, 79 were poisonings with lye, 29 with acids, and 3 with other caustic substances. Of the patients poisoned with lye, 78 were females and 1 was a male. The average age of the women was 22 years, the youngest being 14 and the oldest 59. The man's age was 25 years. The alkali used was always sodium hydroxide. All of the patients poisoned with acids were women. Of these, the average age was 24 years, the youngest being 17 and the oldest 47. The acid used in 24 instances was hydrochloric acid, in 2, sulphuric acid, in 2, oxalic acid, and in 1, formic acid. Because of the similarity of effect with acid poisonings there were also classed with this latter group a case of potassium permanganate poisoning, a case of zinc chloride poisoning, and a case of formalin poisoning.

In 18 of the patients poisoned with alkali and in 9 poisoned with acid no pathologic changes in the esophagus or stomach could be found. In the remainder, more or less outspoken alterations could be demonstrated, in the less severe cases only spasmodic

manifestations were seen, while in the severe cases more or less widespread cicatricial stenoses were found

The most widespread and severe lesions predominated among the alkali poisonings. This seems to be due to the greater viscosity of the lye preparations so that they tend to adhere all along the route, and to the wet, disintegrative type of necrosis (colliquation) produced, so that the necrotic surface itself tends to soak up the caustic liquid like blotting paper. The acids, on the contrary, produce a dry crustlike necrosis of the tissues (coagulation) which protects the deeper structures.

In this material it was found that only the alkalis presented esophageal lesions of lasting character. In fact, in 3 of the patients the lye seemed to have penetrated so deeply as to paralyze the nerve supply governing the muscular action of the esophagus. In these cases the patient could not even swallow liquids, yet the largest sound could be passed all the way to the stomach. Roentgenology disclosed a uniformly cylindrical esophagus without a trace of peristalsis. This condition the author designates "inactive esophagus," and he warns that these cases demand gastrostomy just as early and urgently as the cases of impermeable stricture. Another peculiarity of the alkalis was their ability to get through the pyloric sphincter and produce lesions of the duodenum. In 4 instances high grade stenosis of the duodenum could be demonstrated in the cases of alkali poisoning. This finding would seem to be of differential diagnostic value as between alkali and the acid poisonings.

The acids, on the other hand, tended to pass rapidly through the esophagus and along the lesser curvature of the stomach, to be eventually held up at the pylorus and produce the well-known isolated lesions of this region of the stomach. Another finding of possible differential-diagnostic interest in the acid poisonings was the peculiar honeycomb appearance of the antrum of the stomach, which tended to disappear as the superficial injuries to the gastric mucosal folds healed.

On the whole, however, there were no constant roentgenologic findings permitting a definitive distinction between the lesions caused by acids and those caused by alkalis. In fact, there was no definite differentiation between the lesions of caustic poisonings and other pathologic conditions of the stomach, such as cicatricial changes produced by peptic ulcer, and the cicatricial stenotic forms of fibrous carcinoma, lues, lymphogranulomatosis, actinomycosis, and even of certain types of gastric changes in lymphatic leucemia.

Therefore, the differential diagnosis of caustic poisoning will frequently depend ultimately upon the history, and such amnesic data must consequently be sought diligently in every case of cicatricial lesion of the gastrointestinal tract. It is surprising how often such data are forgotten or suppressed through a feeling of shame.

JOHN W. BRENNAN, M.D.

Gastric Dyskinesia Roentgen Kymographic Semeiology (Le discinesie gastriche Semeiotica roentgenchumografica) ANTONIO LURA. *Arch ital mal app diger*, 1949, 15 3

Contrary to gastrography, roentgenologic examination is not able to furnish manometric data concerning the endogastric pressure, but it allows a morphologic and functional study of the stomach. Of both methods, one is not a substitute for, but a supplement to, the other. Only a combination of roentgenologic and clinical findings is able to give the true picture of the condition.

While roentgen cinematography never gained popularity, roentgen kymography has proved its value in the study of gastric function under normal and pathologic conditions. Two groups of movements of the stomach may be distinguished:

1. Passive (1) pulsations transmitted to the stomach by the heart and large blood vessels, and (2) respiratory movements.

Active (1) peristaltic movements accompanied by either a single, rapid oscillation of the tonus, or its multiple variations, and (2) oscillations of the tonus without peristaltic movements.

Kymographic studies offer the opportunity of exact physicomathematical investigation of the peristalsis. The shape of the curves, their length, amplitude, frequency, and velocity of propagation can be studied.

Individual variations of the gastric motility, which depend upon constitutional factors, should not be mistaken for pathologic dystonia.

A circumscribed hypertonus and hyperperistalsis confined to the antrum may be observed in patients with chronic appendicitis. This is an example of the value of kymographic studies. A relative immobility of the gastric plicae is observed in individuals suffering from hypertrophic gastritis. Absence of peristalsis at the site of an ulcer, local spasm, and the presence of a niche are characteristic for this condition. Kymography is particularly valuable for the detection of scirrhous carcinoma because it visualizes the alterations of the gastric motility much better than the customary roentgenograms.

JOSEPH K. NARAT, M.D.

An Analysis of X-Ray Findings in 405 Cases of Benign Gastric and Pyloric Ulcer WALTER A. RUSSELL, SYDNEY WEINTRAUB, and HAROLD L. TEMPLE. *Radiology*, 1948, 51 790

The authors state that the primary purpose of their study was (a) to determine the most frequent sites of benign gastric ulcers, and (b) to discover the reasons for the differences in location as reported by the radiologist, the surgeon, and the pathologist. The material consists of 429 gastric and pyloric ulcers in 405 patients.

The confusion that exists in the anatomical terminology of the component parts of the stomach is pointed out and suggestions for standardization are made. A diagram is included. The term "antrum" is applied by the authors to that portion of the stom-

ach between the incisura angularis and the pylorus, the distal 2.5 cm of this area being called the prepyloric area. The word "pylorus" is applied only to the aperture between the stomach and duodenum. Use of the terms "parapyloric" and "juxtapyloric" ulcer is deplored.

The contradictory reports on the incidence of pyloric ulcers could be avoided by accepting the following criteria: "(a) lengthening of the pyloric sphincter (wide interval), (b) distortion of the pyloric sphincter (crooked stem), (c) a niche, usually small, located within the elongated canal."

Most of the discrepancies between surgical and radiological localization of the ulcer occurred in the region of the pylorus. The authors believe that relaxation due to anesthesia, the variation in the course of the pyloric vein, and distortion by adhesions place the surgeon at a disadvantage as compared to the radiologist since, during his examination, there is a distinct dividing line between the stomach and duodenum. The results of surgical and radiologic localization are compared in 198 cases in which operation was performed a few days following roentgen examination. There was agreement in 135 cases and disagreement in 22 cases, in 9 of which the roentgen localization was verified by the pathologist, whereas the surgical localization was verified in only 1 case. In 30 cases the ulcers were not localized by surgery.

Of the 429 ulcers, 64.8 per cent occurred on the lesser curvature of the body, including the region of the incisura angularis, 8.2 per cent were prepyloric, 18.9 per cent occurred at the pylorus, 7.5 per cent were in that portion of the antrum proximal to the prepyloric area. Two ulcers were in the fundus.

The size of the ulcer was determined in 310 cases, 88.7 per cent of these ulcers were found to measure less than 2.5 cm, and 11.3 per cent (35) were 2.5 cm or larger. Of these 35, 26 were proved benign and 5 others were followed up medically for 5 years or longer.

A comparison of medical and surgical treatment showed that good results were obtained in 92.1 per cent of patients who were treated by gastric resection as compared with 40.8 per cent of patients who were treated medically.

X-Ray Observations Before and After Vagotomy

WARREN W. FUREY *Radiology*, 1948, 51: 806

The current literature with regard to vagotomy is discussed. The controversial reports of the efficacy of this operation in the treatment of peptic ulcer are mentioned, and a summary is given of the results of vagotomy in 40 cases.

Patients were observed for a period of 5 years, with follow-up examinations at from 6 to 18 months postoperatively. The transabdominal approach was used in 30 cases and the transthoracic route in 10 cases. The average duration of symptoms was 10 years.

Ten patients registered "minor" complaints postoperatively, in 3 patients the operation was considered a failure because of recurrence of symptoms.

The striking discrepancy between roentgen findings and symptoms postoperatively is pointed out. Persistent deformity of the duodenum or ulcer niche, absence of peristalsis, and marked retention were repeatedly observed postoperatively in patients who had no symptoms. Because of these complications, the authors believe that more time is necessary for a complete evaluation of the method.

Twelve cases are reported.

PAUL R. NOBLE, M.D.

The Diagnosis of Internal Genital Tuberculosis in the Male by Roentgenograms (Die Diagnose der inneren maennlichen Genitaltuberkulose im Roentgenbild) WERNER STAEBLER *Helvet. chir. acta*, 1948, 15: 476

On the basis of his experience with more than 300 vesiculographies and urethroographies for various diseases of the genital system, the author believes that the extent of dissemination of tuberculosis in the inner genitalia in the male can be determined with a certain degree of accuracy by means of roentgenograms. The technique of vesiculography is described and the x-ray findings are illustrated.

It is possible to demonstrate early changes in the seminal vesicles, vas deferens, and ampulla, and also in the prostate gland by this means. However, small foci in the prostate may not be revealed. It is possible to determine whether the tuberculous process is unilateral or bilateral, and to carry out operative measures to meet the individual problem. The author found that internal dissemination is frequently unilateral and can be checked by operative intervention.

JOHN L. LINDQUIST, M.D.

The Evaluation of the Lesser Circulation as Portrayed by the Roentgenogram W. WALTER WASSON *Am. J. Roentg.*, 1949, 61: 30

Until recently, investigations of the lesser circulation have been carried out by physiologists and through animal experimentation. A thorough knowledge of chest anatomy, physiology, variations, and diseases is essential for a final evaluation of the lesser circulation.

Chest films should be taken in deep inspiration. A chest film, in expiration, will serve to demonstrate emphysema. All film exposures should be taken no slower than one-twentieth of a second, or the heart and vessel motion will cause a blurring of the image. Multiple views frequently are necessary in order to show the many anatomical structures.

Right ventricular enlargement is a late manifestation of increased tension within the lesser circulation. The ratio of thickness of the right to left ventricular wall may be used to calculate lesser circulation pressure, provided the greater circulation pressure is known.

Pulmonary arteries under pressure become dilated and pulsate—"hilar dance." Lymph stasis or edema displaces air from air sacs and is characteristic of increased lesser circulation pressure, capillary permeability, or lymph stasis.

Most lesions of the lesser circulation are secondary to other chest diseases. There are four main classes of disease of the lesser circulation (1) heart disease, (2) vascular sclerosis, arteriovenous fistula, emboli, tumors, and allergic response, (3) pulmonary fibrosis, tuberculosis, cor pulmonale, or any pulmonary disease which may secondarily interfere with lesser circulation, and (4) deformity of the thoracic cage, obesity, postoperative or posttraumatic chest changes

MAURICE D SACHS, M D

Studies on the Harmful Effects of Thorotrast on the Tissues (Untersuchungen ueber die gewebeschaedigende Wirkung des Thorotrast) WERNER WACHSMUTH. *Chirurg*, 1948, 19 390

A 28 year old medical student was injured in the left temporal region by a shell splinter. A brain abscess developed with cerebral prolapse and osteomyelitis of the temporal bone. A well known neurologic surgeon injected thorotrast percutaneously into the carotid artery, evidently there was some paravascular spilling, for there subsequently developed at the spot a small apple-sized, dense, nonsensitive tumor. The arterial pulsations on that side could not be felt and the patient complained of dizziness, visual disturbances, fainting sensations, tinnitus, and sweating attacks.

Operation disclosed a much more extensive process than was at first presumed. The dense connective tissue masses enveloped the common carotid artery from the region of the clavicle to the point of arterial bifurcation in the neck. The cicatricial masses were removed and the artery began to pulsate again, however, it seemed peculiarly inelastic and thickened. Nineteen days after the operation profuse bleeding developed from the artery and the clavicle had to be cut in order to find a place, low down, where the ligature would not cut through the arterial wall.

It was on the thorotrast-infiltrated tissues removed at these operations that the physicist Kulenkampff made his measurements of the gamma radiations of the thorium in the thorium dioxide contained in this preparation. Although the best apparatus was not available for this type of work, nevertheless, by comparing the results of the measurements of the infiltrated tissue in an ionization chamber, and making allowance for every known source of error, he was able to show that the thorium in these tissues was giving off ten times the irradiation permitted as the minimum for safety.

The roentgenologic examination showed the extensive infiltration of the thorotrast not only locally in the cicatricial tissues but also in the lymph glands, within the walls of the carotid artery and, eventually, in the spleen. From these observations the author concludes that thorotrast as a means of demonstrating the blood vessels is contraindicated, unless the patient has no more than a few years to live anyhow, and that percutaneous injection of the material, when a certain amount of perivascular spilling cannot be avoided, is absolutely contraindicated in any case.

JOHN W BRENNAN, M D

Concerning Thorotrast Injuries and the Sarcoma Peril of Thorotrast (Ueber Thorotrastschaeden und Thorotrastsarkomgefahr) K H BAUER. *Chirurg*, 1948, 19 387

The first article in condemnation of thorotrast used as a contrast material appeared in 1943 (*Chirurg*, 1943, 15 204). Recently, Kuhlendahl, in this same journal (*Chirurg*, 1948, No 9) has defended its further use but "under strictest indications," because of its allegedly great scientific usefulness in the past and the absence of positively proved injury to the human being. Stimulated by this article, the author feels impelled to publish what further proofs he now has in support of his previous contentions.

In the first place the author does not think that the scientific usefulness of thorotrast in the past has been so great. It has been proved that, experimentally at least, every length of wave from the ultraviolet on down to the gamma waves has a carcinogenic action, and that thorotrast itself increases the list of approximately 300 cancerogenic novae. Experience in general, including the author's own, teaches that in 90 per cent of the instances in which the preparation is used, such employment is unnecessary and that in the remaining 10 per cent it can be replaced by something else. Finally, it is insisted that thorotrast is harmful even to the human being and such harm grows progressively with the passage of time.

That this contrast medium is harmful to man has been shown by the figures from the author's own service at Heidelberg, where in the past 5 years 35 cases of thorotrast injury of the severest type have been demonstrated. Now the demonstration of the actual production of a sarcoma of the liver has been made by MacMahon, Murphy, and Boates (*Am J Path*, 1947, 23 585). Karcher had already shown the carcinogenic action of this chemical in mice, rats, guinea pigs, and rabbits, the latent period ranging from 9 to 39 months, in the human being the comparable period would be from 12 to 18 years. It is just 12 years since the medium was used in the American case, just cited. Therefore, the cumulative effects of the preparations used during all the years since 1933, when they began to gain wide recognition, may now be expected to appear. This prospect creates a problem for the future, and it is peculiarly a German problem since in other countries, notably the United States in 1932, thorotrast was openly condemned. This problem is designated the iatrogenic thorotrast problem.

As regards the question as to what is to be done about this condition of affairs, the work of the physicist Kulenkampff is cited. He proves that the irradiation effect of thorotrast amounts to about 6 roentgens daily, which is about ten times the minimal safe dosage for the contiguous tissues. From this it develops that any further irradiation (as recommended by some authors for the combating of thorotrast injury) would only add to the burden of such tissues. Jacob and Wachsmann (*Klin Wschr*, 1948, 26 20) have shown that under the usual conditions

in which thorotrast has been used, the further irradiation of its deposits would increase the effects to as much as 50,000 roentgens, and such a procedure would not be therapy but syncarcinogenesis.

It is therefore contended that not only should thorotrast disappear from use as a contrast medium but discussions concerning its merits and demerits should cease. "What will the world think of German medicine when it sees in the medical periodicals that this preparation is still being used for 'neurographies,' 'spermatographies,' 'mammographies,' 'pulmo-radiographies,' and all the other kinds of 'graphies'?" To say that one has not seen any complications from roentgenography with thorotrast and that others have not observed any serious complications is begging the question. The drug is at first well tolerated, herein lies its curse. It is the late injuries that one must consider the thorotrast granuloma, the injury to the liver, spleen, lymph glands, vascular system (perivascular granulomas), and the blood-forming organs, and, finally, the danger of sarcoma.

Certainly, thorotrast should not be used as a contrast medium without the express consent of the patient.

JOHN W. BRENNAN, M.D.

Should We Continue to Use Thorotrast for Angiographic Purposes (Darf das Thorotrast zur Angiographie heute noch angewandt werden)? HANS KUHLEDAHL *Chirurg*, 1948, 19: 396

Since the work of Ruland (*Chirurg*, 1947, 17:18-540) the question is no longer whether it is wise to use thorotrast for angiography of the cerebral vessels, but whether it is ethical for the physician to use the preparation at any time. Neurologic surgery, for which this contrast medium was used most extensively, can hardly be thought of as existing in its present form without the aid of this most valuable adjunct. It is true that thorotrast is not the ideal medium, and with the advent of a better one it will without question be discarded. This better medium can be confidently expected to appear in the not too distant future. Vasoselectan is now in the experimental stage. Parabrodil is not a solution of the problem.

Ruland's work has not succeeded in proving a sarcomatous change in the tissue of his experimental animals, and his conclusions as to such a possibility are therefore hypothetical in character. It should be emphasized ever anew that the value of thorotrast in the fields of research and practice has, up to the present, been of enormous consequence, and such value has not as yet been challenged by any incontrovertible proof that its skilful and intelligent use (in the percutaneous injection method, and, for instance, in hepatography) has been harmful to the human subject.

The argument concerning the long latent period before the irradiations effect their harmfulness does not apply, at least not in the matter of arteriography in the diagnosis of brain tumors. Is not the lack of diagnostic certainty in such conditions as cerebral aneurysm or expanding growths within the skull

even more harmful, even more an immediate threat to life than the hypothetical injuries of thorotrast? Merely to cite one instance when preliminary arteriography leads to correctly timed interruption of the vascular supply of a bloody meningioma and thus lowers the operative mortality essentially, the use of thorotrast surely is justified.

It is true that the alarming reports from the studies of Ruland demand that only an absolutely certain intravascular application of the medium is permissible, that the huge quantities used in hepatographies and lenographies be proscribed, that the preparation not be used in tests of the efficacy of the circulation such as those carried out on the peripheral vessels of the extremities, that any injected quantity be limited to not more than 14 to 20 c.c., and that thorotrast not be used (as far as possible) in young adults and children. However, in patients with a life expectancy which does not exceed the hypothetical latent period the advantages of thorotrast should not be underestimated.

JOHN W. BRENNAN, M.D.

The Role of Irradiation in the Management of Carcinoma of the Breast EUGENE P. PENDERGRASS and DAVID KIRSH *Radiology*, 1948, 51: 767

By the inclusion of 406 cases of carcinoma of the breast which were seen during the period from 1932 to 1939, the authors have brought up to date a survey of the cases seen in the Radiologic Clinic of the University of Pennsylvania since 1902. Previous communications included 387 cases seen from 1902 to 1931.

The material is classified according to Steintal's plan, which was used previously, although the authors express preference for Portman's classification as well as his "criteria of curability."

A definition of terms is included. The criteria for operability and inoperability set forth by Haagensen and Stout are recommended. "Prophylactic irradiation" is a term reserved for radiation over areas of lymphatic drainage in which there is no evidence of metastasis.

The technique of irradiation for six periods of time is given in detail.

Of the 406 patients whose cases are reported, 350 were treated surgically, 188 received postoperative roentgen irradiation to the operative site and lymph node areas, while 162 received no irradiation except when metastatic or recurrent disease developed. Irradiation alone was used in 56 cases because (1) the lesion was inoperable, (2) there was some medical contraindication, or (3) surgery was refused.

Ten tables listing the 5 year survivals according to successive periods, Steintal's classification, age group, type of treatment, and effect of metastases, are included. These were subjected to statistical analysis, and the authors concluded that the reported increase of 26 per cent in the 5 year survival rate from 1902 to 1931, to 42 per cent from 1932 to 1939 is statistically significant. They attribute this to improved treatment, both surgical and radiological.

They believe that lesions are seen earlier and that better selection of cases suitable for operative care is being exercised

A comparison of the survival time of patients who received only surgical treatment with that of patients who received postoperative irradiation showed no significant difference regardless of whether the contralateral side was irradiated as well as the side operated upon. This is also true of cases compared as to histological evidence of axillary metastases. Irradiation further fails to influence the development of metastases or recurrence.

Pleural effusion developed in 26 patients, 14 of whom had received previous irradiation. Sixteen (4%) patients had herpes zoster. Nontoxic goiter was observed in 9 patients and toxic goiter in 12, 13 of the 21 survived more than 5 years. A second primary cancer occurred in 20 (4%) of these patients. The lesions were distributed over ten locations, and in only one case did the lesion appear in the opposite breast 11 years after the previous mastectomy.

The authors used x-ray castration in 38 patients after the appearance of metastatic disease. They believe that this method of castration should be used only at that time.

Lymphedema of the arm developed in 59 (34%) of the patients, 34 of whom had received irradiation.

The authors state that at the present time irradiation in the management of carcinoma has been relegated to a palliative role. Suggestions pertaining to the treatment of bone pain, dyspnea, cough, and pleural effusion due to metastasis, are presented.

In summary, the authors state that no significant improvement was observed in the 5 year survival rate which could be attributed to postoperative irradiation, and that there appears to be a relatively high incidence of herpes zoster which probably is due to metastatic involvement of the spinal ganglion.

PAUL R. NOBLE M D

Intravaginal Roentgen Therapy in Cancer of the Cervix Uteri

GRAY H. TWOMBLY and J. ALLEN CHAMBERLIN *Radiology*, 1949, 52 14

The authors present the results of treatment of cancer of the cervix in 104 of 113 patients treated at the Memorial Hospital, New York. In these patients intravaginal x-ray radiation was substituted for intravaginal radium application in a "bomb" placed against the cervix.

During 1943 and 1944, four treatments of 500 roentgens each, total 2,000 roentgens, were given directly to the cervix, usually through a cone 4 cm. in diameter. The fornices were treated with a small cone 3 or 3.5 cm. in diameter, which gave 750 roentgens at each treatment for four treatments, or a total of 3,000 roentgens to each area. The tube was directed outward at an angle of 30 degrees. Effort was made to avoid overlapping. The factors used were 120 kv., 3 mm. of aluminum filter, and 25 cm. target-skin distance. The intravaginal treatments were given simultaneously with divided dose external roentgen therapy and were followed by the

intracervical application of radium for 3,000 hours.

The use of intravaginal cones for roentgen therapy in cancer of the cervix has three obvious advantages. It gives a more uniform distribution of radiation, does not pass through normal tissue which attenuates the quality and diminishes the quantity of radiation which reaches the parametria and the pelvic lymph nodes, and it can be done in such a fashion that the irritation and permanent changes which are usually produced in the bladder and rectum by large quantities of external roentgen therapy are avoided to a great extent.

The 3 year or longer survival was obtained in 36.5 per cent, these patients were apparently free of cancer. This 3 year salvage is as good or better than previous 3 year figures obtained by other forms of therapy in this clinic.

The authors' experience has shown that the quantity of irradiation in intravaginal cone therapy can be increased considerably over the amounts previously given, when the external therapy and radium therapy is kept constant. At present, patients are receiving 750 roentgens to each of three vaginal cones, the factors being 250 kv., 55 cm. target-skin distance and 2 mm. of copper, half value layer.

FRANK L. HUSSEY, M D

Review of 10 Years Experience with Transvaginal Roentgen Therapy

RALPH M. CAULK. *Radiology*, 1949, 52 26

The author analyzes the results of treatment of unselected patients at Warwick Clinic (Wash. D. C.) with carcinoma of the cervix in whom there was an absolute 5 to 10 year survival of 35 per cent. Of this series of patients, 79 per cent received transvaginal roentgen therapy either alone or supplemented by radium, external roentgen therapy, or both. Two pieces of x-ray apparatus were employed for the transvaginal therapy. One machine operated at 140 kv. (peak), with 8 ma., 3 mm. of aluminum filter (added), half value layer, 3.85 mm. of aluminum. The anode-cervix distance varied from 24 to 28 cm. The other machine operated at 220 kv. (peak), with 5 ma., 0.5 mm. of copper filter (added) half value layer equivalent to 10 mm. of copper. The anode-cervix distance varied from 37 to 41 cm. The anode-cervix distance and the size of the irradiated field varied with the length and diameter of the speculum and the diameter of the master cone aperture.

With the patient in the lithotomy position the cervix was exposed to the x-rays by use of a Ferguson speculum. No effort was made to direct the beam to either of the fornices or the parametria. The introitus was adequately protected. A daily dose of 800 roentgens were given. The total dose varied over the years from 5,000 to 8,000 roentgens. In early cases which were considered suitable for transvaginal therapy only, many received small doses of external radiation (from 50 to 100 roentgens). This has since been abandoned. The

They believe that lesions are seen earlier and that better selection of cases suitable for operative care is being exercised.

A comparison of the survival time of patients who received only surgical treatment with that of patients who received postoperative irradiation showed no significant difference regardless of whether the contralateral side was irradiated as well as the side operated upon. This is also true of cases compared as to histological evidence of axillary metastases. Irradiation further fails to influence the development of metastases or recurrence.

PAUL R. NOBLE, M.D.

Intravaginal Roentgen Therapy in Cancer of the Cervix Uteri. GRAY H. TWOMBLY and J. ALLEN CHAMBERLIN. *Radiology*, 1940, 52, 14.

The authors present the results of treatment of cancer of the cervix in 104 of 113 patients treated at the Memorial Hospital, New York. In these patients intravaginal x-ray radiation was substituted for intravaginal radium application in a "bomb" placed against the cervix.

During 1943 and 1944, four treatments of 500 roentgens each, total 2,000 roentgens, were given directly to the cervix, usually through a cone 4 cm in diameter. The fornices were treated with a small cone 3 or 3.5 cm in diameter, which gave 750 roentgens at each treatment for four treatments, or a total of 3,000 roentgens to each area. The tube was directed outward at an angle of 30 degrees. Effort was made to avoid overlapping. The factors used were 120 kv, 3 mm of aluminum filter, and 25 cm target skin distance. The intravaginal treatments were given simultaneously with divided dose external roentgen therapy and were followed by the

intracervical application of radium for 300 hours.

The use of intravaginal cones for roentgen therapy in cancer of the cervix has three characteristics: it gives a more uniform distribution of radiation; it gives radium and gives it directly to the lesion, without passing it first through normal tissue; it intensifies the quality and diminishes the quantity of radiation. It irradiates quite effectively the parametral and the pelvic lymph nodes, and it can be used in such a fashion that the irritation and hemorrhages which are usually produced in the vagina and rectum by large quantities of external therapy are avoided to a great extent.

The 3 year or longer survival was obtained in 10 patients, or 36.5 per cent, these patients were entirely free of cancer. This 3 year salvage rate is better than previous 3 year figures for all other forms of therapy in this clinic.

The authors' experience has shown that the intensity of irradiation in intravaginal cone therapy can be increased considerably over the amount previously given, when the external therapy and radium dose is kept constant. At present, patients are receiving times 750 roentgens to each of three vaginal cones, the factors being 250 kv, 55 cm target-skin distance, and 2 mm of copper, half value layer.

FRANK L. HUSSEY, M.D.

Review of 10 Years Experience with T. Roentgen Therapy. RALPH M. CAULK. *Radiology*, 1949, 52, 26.

The author analyzes the results of treatment of 100 unselected patients at Warwick Clinic (Washington, D.C.) with carcinoma of the cervix in whom L.D.C. was an absolute 5 to 10 year survival of 35 per cent. Of this series of patients, 79 per cent received intravaginal roentgen therapy either alone or supplemented by radium, external roentgen therapy, or both. Two pieces of x-ray apparatus were employed for the transvaginal therapy. One machine operated at 140 kv (peak), with 8 ma, 3 mm of aluminum filter (added), half value layer, 3.85 mm of aluminum. The anode-cervix distance varied from 24 to 28 cm. The other machine operated at 220 kv (peak), 10 ma, 0.5 mm of copper filter (added) half value layer equivalent to 1.0 mm of copper. The anode-cervix distance varied from 37 to 41 cm. The anode-cervix distance and the size of the irradiated field varied with the length and diameter of the speculum and the diameter of the master cone aperture.

With the patient in the lithotomy position the cervix was exposed to the x-rays by use of a Ferguson speculum. No effort was made to direct the beam to either of the fornices or the parametria. The treatment was adequately protected. A daily dose of 800 roentgens were given. The total dose varied from 5,000 to 8,000 roentgens. Of the early cases which were considered suitable for intravaginal therapy only, many received small doses of external radiation (from 50 to 100 roentgens). This has since been abandoned. The

The treatment of choice in the management of the stage III, stage IV, selected stage I, and most stage II malignant lesions of the uterine cervix is well planned radium and roentgen therapy

FRANK L. HUSSEY, M.D.

MISCELLANEOUS

Carcinoma of the Cervical Stump WILLIAM E.
COSTOLOW *Radiology*, 1949, 52 41

The author reviews 165 cases of carcinoma of the cervical stump seen at the Los Angeles Tumor Institute, Los Angeles, California, between 1922 and 1947. During this period 1,906 cases of carcinoma of the cervix were seen. The incidence of carcinoma of the stump is thus 8 per cent of the total of 2,071 cases. In 63 of the 165 cases, cancer occurred in the first 2 years after supravaginal hysterectomy and probably should not be classified as true carcinoma of the cervical stump. In the remaining 102 cases the condition was probably true carcinoma of the stump, an incidence of 4.9 per cent of the total number of cervical cancers for the 25 year period.

Radium and x-rays were used in combination in the treatment of practically all patients. The total dosage of radium varied from 4,000 to 5,000 mgm hours. The roentgen therapy was usually begun immediately following the radium cycle. From 1922 to 1934, from 180 to 200 kv were used. Since then from 450 to 500 kv have been employed. The amount of therapy has varied from a tissue dose of from 3,000 to 5,000 roentgens to the midpelvis

A 5 year survival of 32.5 per cent was obtained as shown by the records of 114 of the 168 cases. Of the patients, 18 per cent were alive with disease after 5 years, and 30.5 per cent were alive without evidence of disease. The necessity of thorough examination of the cervix and uterine canal before supravaginal hysterectomy is indicated. Adequate radiation treatment is essential, but care must be taken to avoid rectovaginal and vesicovaginal fistulae.

FRANK L HUSSEY,

They believe that lesions are seen earlier and that better selection of cases suitable for operative care is being exercised

A comparison of the survival time of patients who received only surgical treatment with that of patients who received postoperative irradiation showed no significant difference regardless of whether the contralateral side was irradiated as well as the side operated upon. This is also true of cases compared as to histological evidence of axillary metastases. Irradiation further fails to influence the development of metastases or recurrence.

Pleural effusion developed in 26 patients, 14 of whom had received previous irradiation. Sixteen (4%) patients had herpes zoster. Nontoxic goiter was observed in 9 patients and toxic goiter in 12, 13 of the 21 survived more than 5 years. A second primary cancer occurred in 20 (4%) of these patients. The lesions were distributed over ten locations, and in only one case did the lesion appear in the opposite breast 11 years after the previous mastectomy.

The authors used x-ray castration in 38 patients after the appearance of metastatic disease. They believe that this method of castration should be used only at that time.

Lymphedema of the arm developed in 59 (34%) of the patients, 34 of whom had received irradiation.

The authors state that at the present time irradiation in the management of carcinoma has been relegated to a palliative role. Suggestions pertaining to the treatment of bone pain, dyspnea, cough, and pleural effusion due to metastasis, are presented.

In summary, the authors state that no significant improvement was observed in the 5 year survival rate which could be attributed to postoperative irradiation, and that there appears to be a relatively high incidence of herpes zoster which probably is due to metastatic involvement of the spinal ganglion.

PAUL R. NOBLE, M.D.

Intravaginal Roentgen Therapy in Cancer of the Cervix Uteri GRAY H. TWOMBLY and J. ALLEN CHAMBERLIN. *Radiology*, 1949, 52, 14

The authors present the results of treatment of cancer of the cervix in 104 of 113 patients treated at the Memorial Hospital, New York. In these patients intravaginal x-ray radiation was substituted for intravaginal radium application in a "bomb" placed against the cervix.

During 1943 and 1944, four treatments of 500 roentgens each, total 2,000 roentgens, were given directly to the cervix, usually through a cone 4 cm in diameter. The fornices were treated with a small cone 3 or 3.5 cm in diameter, which gave 750 roentgens at each treatment for four treatments, or a total of 3,000 roentgens to each area. The tube was directed outward at an angle of 30 degrees. Effort was made to avoid overlapping. The factors used were 120 kv, 3 mm of aluminum filter, and 25 cm target-skin distance. The intravaginal treatments were given simultaneously with divided dose external roentgen therapy and were followed by the

intracervical application of radium for 3,000 mc hours.

The use of intravaginal cones for roentgen therapy in cancer of the cervix has three obvious advantages: it gives a more uniform distribution of radiation than does radium and gives it directly to the lesion without passing it first through normal tissue which softens the quality and diminishes the quantity; it irradiates quite effectively the parametrial tissues and the pelvic lymph nodes, and it can be directed in such a fashion that the irritation and permanent changes which are usually produced in the bladder and rectum by large quantities of external roentgen therapy are avoided to a great extent.

The 3 year or longer survival was obtained in 38 patients, or 36.5 per cent; these patients were apparently free of cancer. This 3 year salvage is as good or better than previous 3 year figures obtained with other forms of therapy in this clinic.

The authors' experience has shown that the quantity of irradiation in intravaginal cone therapy can be increased considerably over the amounts herein given, when the external therapy and radium dosage is kept constant. At present, patients are receiving 6 times 750 roentgens to each of three vaginal fields, the factors being 250 kv, 55 cm target-skin distance, and 2 mm of copper, half value layer.

FRANK L. HUSSEY, M.D.

Review of 10 Years Experience with Transvaginal Roentgen Therapy RALPH M. CAULK. *Radiology*, 1949, 52, 26

The author analyzes the results of treatment of 262 unselected patients at Warwick Clinic (Washington, D.C.) with carcinoma of the cervix in whom there was an absolute 5 to 10 year survival of 35 per cent. Of this series of patients, 79 per cent received transvaginal roentgen therapy either alone or supplemented by radium, external roentgen therapy, or both. Two pieces of x-ray apparatus were employed for the transvaginal therapy. One machine operated at 140 kv (peak), with 8 ma, 3 mm of aluminum filter (added), half value layer, 3.85 mm of aluminum. The anode-cervix distance varied from 24 to 28 cm. The other machine operated at 220 kv (peak), 20 ma, 0.5 mm of copper filter (added) half value layer, equivalent to 10 mm of copper. The anode-cervix distance varied from 37 to 41 cm. The anode-cervix distance and the size of the irradiated field varied with the length and diameter of the speculum and the diameter of the master cone aperture.

With the patient in the lithotomy position the cervix was exposed to the x-rays by use of a Ferguson speculum. No effort was made to direct the beam into either of the fornices or the parametria. The introitus was adequately protected. A daily dose of 800 roentgens were given. The total dose varied over the years from 5,000 to 8,000 roentgens. Of the early cases which were considered suitable for transvaginal therapy only, many received small daily doses of external radiation (from 50 to 100 roentgens). This has since been abandoned. The sur-

PHYSICOCHEMICAL METHODS IN SURGERY

vival data presented are based on transvaginal roentgen therapy delivered at 200 kv p

The complications consisted of bowel reactions, local necrosis of the cervix, vulvar and vaginal necrosis, or both, and vaginal atresia. The author considers that transvaginal roentgen therapy is an ideal substitute for local cervical radium application in all cases in which it can be practicably applied

FRANK L. HUSSEY, M D

RADIUM

Immediate and Late Results of Intracavitary Radium Therapy for Malignant Lesions of the Cervix
vix HARRY H. BOWING *Radiology*, 1949, 52 1

The author presents data prepared by the Division of Biometry and Medical Statistics of the Mayo Clinic, concerning patients with malignant disease of the uterine cervix treated at the Clinic by irradiation during the period from 1915 through 1944.

During the period of inquiry, 3,798 patients received various types of radium treatment. Of these, 2,246 (59.1 per cent) received initial radium therapy and supplemental roentgen therapy, and they are the patients chiefly considered in this discussion.

The stage of the lesion was recorded in 2,146 cases as follows: stage I (lesions confined to cervix), 13 per cent; stage II (moderate local invasion), 14.3 per cent; stage III (extensive local invasion), 66.1 per cent; stage IV (massive local invasion), 18.4 per cent of the classified group.

In the main, the initial radium therapy employed may be defined as an intensive broken-dose procedure, designed for cure or palliation, applied in a rather brief period. To give the radium, the American type of tube containing 50 mgm of radium sulfate (element) was employed, and treatment was supplemented by a course of roentgen therapy from a 200-kv installation. The total treatment time is about 21 days for the average lesion of stage III.

Five-year survival rates, according to the stage of lesion, for 1,631 traced cases were as follows: 58.8 per cent for lesions of stage I, 65.3 per cent for lesions of stage II, 33.7 per cent for lesions of stage III, 16.5 per cent for lesions of stage IV, 25.1 per cent for modified lesions (previous treatment elsewhere), and 42.2 per cent for a small group in whom the

stage of the lesion was not recorded. The 5 year survival rate for all patients traced was 32.8 per cent.

For various reasons, about 2 per cent of the patients referred to the Section on Radium Therapy were not treated. The hospital mortality was in the range of 1 per cent.

The treatment of choice in the management of the stage III, stage IV, selected stage I, and most stage II malignant lesions of the uterine cervix is well planned radium and roentgen therapy.

MISCELLANEOUS

Carcinoma of the Cervical Stump WILLIAM L. COSTLOW *Radiology*, 1949, 52 41

The author reviews 165 cases of carcinoma of the cervical stump seen at the Los Angeles Tumor Institute, Los Angeles, California, between 1922 and 1947. During this period 1,906 cases of carcinoma of the cervix were seen. The incidence of carcinoma of the stump is thus 8 per cent of the total of 2,071 cases. In 63 of the 165 cases, cancer occurred in the first 2 years after supravaginal hysterectomy and probably should not be classified as true carcinoma of the cervical stump. In the remaining 102 cases the condition was probably true carcinoma of the stump, an incidence of 4.9 per cent of the total number of cervical cancers for the 25 year period.

Radium and x-rays were used in combination in the treatment of practically all patients. The total dosage of radium varied from 4,000 to 5,000 mgm hours. The roentgen therapy was usually begun immediately following the radium cycle. From 1922 to 1934, from 180 to 200 kv were used. Since then from 450 to 500 kv have been employed. The amount of therapy has varied from a tissue dose of from 3,000 to 5,000 roentgens to the midpelvis.

A 5 year survival of 32.5 per cent was obtained as shown by the records of 114 of the 168 cases. Of these patients, 18 per cent were alive with disease after 5 years, and 30.5 per cent were alive without evidence of disease. The necessity of thorough examination of the cervix and uterine canal before supravaginal hysterectomy is indicated. Adequate radiatic treatment is essential, but care must be taken to avoid rectovaginal and vesicovaginal fistulas.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Bacteriological Analysis of Plaster Bandages L GREENBERG *Canad M Ass J*, 1949, 60 4

A fatal case of tetanus resulting from contamination of the wound by a plaster cast led to an investigation of plaster of paris bandages taken from all parts of Canada

In all, 194 bandages of this type were taken from 75 hospitals and 43 commercial distributors. These bandages represented products of 14 commercial manufacturers and 14 hospitals which made their own bandages. Aerobic and anaerobic culture were made of all specimens, and each anaerobic culture was tested for virulence by inoculation into a guinea pig

Of the 163 specimens from commercial manufacturers, 111 (68%) were found to harbor anaerobes. Of the 31 specimens prepared by hospitals, 23 (74%) harbored anaerobes. Only one bandage was found to be sterile. There were spore-bearing aerobic bacilli in 177 (91%) of the bandages, many having two or more species. In 108 bandages (56%) *Clostridium welchii* was found, in 18 (9%) *Clostridium sporogenes*, and in 67 (34%) anaerobes of different species

Further analysis of 7 samples of plaster of paris alone showed these specimens to be heavily contaminated with anaerobes and indicated that this material might be the principal source of contamination of the finished bandage

BENJAMIN F LOUNSBURY, M D

Sterilization of Plaster Bandages M O KLOTZ *Canad M Ass J*, 1949, 60 6

The author of this brief article has summarized his hospital's experience with the sterilization of plaster bandages. Autoclaving of the bandages was found to be impractical because of difficulty in maintaining moisture-free conditions. Because autoclaved plaster was found to have very poor setting and holding qualities, that method of sterilization was abandoned

By trial and error an effective dry heat sterilization was devised, utilizing the upper shelves of a gas oven at a temperature of 190 degrees C for an hour and a half. The plaster bandages were left in the original containers, unopened. Temperatures of 200 degrees C tended to char the bandage. Thus far, the lower temperature has produced effective sterilization, but the surgeons complain that the plaster sets and dries more slowly than unsterilized plaster. The variability in the quality of the plaster has resulted in some wastage, but all of these disadvantages are much more than offset by the prophylactic value of having surgically sterile plaster over open wounds

BENJAMIN F LOUNSBURY, M D

Dextran as a Plasma Substitute GUNNAR THORSÉN *Lancet*, Lond, 1949, 1 132

Results with the colloid, dextran, which has been used in Sweden since 1943, are reported. The preparation in present use, "Dextran Ph," is a proprietary preparation. It is a 6 per cent solution of the polydispersoid glucose, polymer dextran, in which most of the molecules have been hydrolytically given a molecular weight conforming to that of albumin, with 0.9 per cent of sodium chloride added to it.

Dextran has been given to 5,000 patients and in a few cases up to 4 liters have been given in a single infusion. Total elimination from the body and nontoxicity are reported. Dextran has been found very useful as a substitute for blood and plasma in cases in which an increase in the blood volume or in the colloid osmotic pressure is desired.

WALTER H NADLER, M D

Dextran as a Plasma Substitute J P BULL, C RICKETTS, J R SQUIRE, W d'A MAYCOCK, and Others *Lancet*, Lond, 1949, 1 134

It was found possible to prepare dextran with a range of molecular size similar to that of the plasma proteins. The solution was well tolerated as an infusion by man and was not pyrogenic, toxic, or antigenic. After infusion into animals and man such dextran was only slowly removed from the plasma in about a week. British dextran was efficacious as a plasma substitute in cases of burns, and produced a sustained increase in the venous return in patients with surgical shock or hemorrhage. There is still doubt about the ultimate fate of dextran in the body and, therefore, it cannot yet be recommended unreservedly for widespread use. However, in the investigation reported it has not been shown to produce any harmful effect on the tissues, and further investigation is recommended.

WALTER H NADLER, M D

The Collateral Circulation J R IFARMONTH *J internal chir*, Brux, 1948, 8 1008

The author emphasizes the importance of maintaining and encouraging the collateral circulation as a part of the treatment of obstructive lesions of the large arteries. The surgeon must be ready from the very beginning to encourage the collateral blood supply and in certain cases to augment it, since his period of usefulness is strictly limited to the critical survival period for each individual tissue after its blood supply ceases to be adequate, a period which varies from a minute or 2 for cerebral tissue to about 24 hours for skin. The possibility of adequate collateral flow depends on the maintenance of adequate blood pressure and on the number and caliber of available collateral vessels. Collaterals function at their best only when they return blood to the main vessels distal to the point of interruption, and the

outlook for nutrition is poor when they merely provide alternative pathways

Pathologic conditions which affect the collateral circulation include arterial spasm. In this connection, Learmonth refers to the observations of MacWilliam on the behavior of living arteries and of segments and strips of excised arteries, and adds his own experiences which show that spasm may occur (1) in an artery of which the extrinsic nerves have been interrupted by spinal anesthesia, (2) in the arteries of a limb in which the peripheral nerves have been interrupted, and therefore the extrinsic nerves of the arterial tree, (3) on arterial puncture through an adventitial coat anesthetized by novocain, at the site of puncture (he has seen spasm extend distally from this point but never proximally), (4) after injury to or exercise of the lower extremity, and (5) in the absence of any local injury. The suggestion is made that the phenomenon of spasm resembles the behavior of the smooth adductor muscle of mollusks, from which it is deduced that the mere relief of vasoconstrictor tone cannot be expected to relax spasm, but that efferent dilator impulses are necessary in addition.

The second factor which interferes with the collateral circulation is consecutive thrombosis, and Learmonth emphasizes that when the possibility of thrombosis is present the immediate treatment of the condition should include the administration of adequate doses of anticoagulant drugs. A further factor influencing the collateral circulation is the previous lodgment of an embolus in diseases such as auricular fibrillation in which multiple emboli are known to occur.

In treatment, nonoperative measures for securing vasodilatation are to be preferred, with sympathectomy as a later possibility to provide against later nutritional disturbances. The measures include rapid restoration of the blood volume, maintenance of adequate blood pressure, avoidance of pain, and the provision of rest and sleep. Ischemic tissues should not be heated but should be maintained at a temperature between 15 and 20°C.

RICHARD KEMEL, M D

The Effect of Injury on Wound Healing PH SANDBLOM *Ann Surg*, 1949, 129 305

Using the tensile strength of wounds to evaluate the healing process (as described by Chlumsky), the author attempts to demonstrate a healing-promoting effect caused by a primary wound. His work shows the definite effect of a primary wound on the tensile strength of a subsequently inflicted symmetrical incision—the secondary wound. The healing-promoting effect is apparent within 12 hours after the primary wound is inflicted, reaches a relative plateau between 5 and 25 days, and disappears between 35 and 45 days.

The author believes that both a stronger coagulum and increased fibroplasia are concerned in the greater tensile strength of the secondary wounds as compared to that of the primary. His work also suggests

that the degree of the healing-promoting effect is related directly to the extent of the primary injury.

JOHN H KAY, M D

Restoration of Grasping Function Following the Loss of All Five Digits BRADFORD CANNON, WALTER C GRAHAM, and JAMES BARRETT BROWN *Surgery*, 1949, 25 420

A method of restoring grasping function without disturbing normal sensation is described. Closure of the unhealed or scarred stump is accomplished with a direct flap, if possible, or with a free skin graft. Elongation of the thumb is accomplished by transplanting the distal portion of the second metacarpal to the end of the first metacarpal. The remainder of the second metacarpal is removed except for the base.

The last stage consists of the formation of a cleft between the first and third metacarpals, which is done after there is good bony union.

The procedure results in good motion and considerable strength, but depends on the capability of movement of the first metacarpal multangular articulation.

JOHN H KAY, M D

Tropical Phagedenic Ulcer The Problem of Phagedenism (A propos de l'ulcère phagédénique tropical Le problème du phagédénisme) M H COSTANTINI *Afrique fr chir*, 1948, No 9-10, 195

The author describes a severe epidemic of tropical ulcer which occurred in Algiers in 1943. Detailed clinical notes made by him and his collaborators were lost so that he was able to present only a general description and discussion in this article.

Tropical ulcer is endemic only in very humid tropical climes of equatorial Africa (Madagascar) and Asia and is not usually seen in Algiers. Most of the afflicted in this tremendous epidemic of 10,000 cases were stevedores and workers at the airport. During the last war, Algiers was the site of very intensive traffic. Goods from the French equatorial colonies were unloaded here in great amount. This fact was probably responsible for the outbreak.

Although it has been known for a long time that a combination of fusiform bacilli in symbiosis with a special kind of Spirochaeta is present in the ulcers, a great many problems have not yet been solved. The ulcer always originates from an insignificant wound or scratch, in most cases on the feet or legs, sometimes on the hands and forearms. It has never been observed on the trunk. It grows with tremendous rapidity and destroys, often within a few days, the subcutaneous tissue, fasciae, and muscles. It often exposes the periosteum and the bone and causes necrosis of the bone. Its borders are undermined and its surface is covered with a thin putrid exudate of a cadaveric odor. Bacteriologic examination of the exudate reveals enormous masses of staphylococci and streptococci in addition to the spirochetes and fusiform bacilli. In spite of this severe infection and the large extent of the ulcer, the general condition is good, the regional lymph nodes

are not affected, and no complications such as gas gangrene, diffuse phlegmon, or septicemia have ever been observed. It is remarkable that these enormous open wounds never bleed. Even in the excision of excessive granulations at the border of the ulcer with the electrocautery, no bleeding takes place.

The patients complain of severe lancinating pains which interfere with their sleep. These pains are the first sign of the affection and often start before the ulcer has developed. They have all the characteristics of sympathetic pains and cease temporarily after lumbar or perifemoral infiltration.

Biopsies taken by the author from the borders of the ulcer revealed that all the arterioles and venules were obliterated. The lumina were closed by thrombi, and the vessels were enclosed by a perivascular inflammatory sheath. Also, the lymph vessels were obliterated. The author assumes that the complete obliteration of all the small blood and lymph vessels accounts for the clinical symptoms: the rapid growth of the ulcer, the relatively good general condition, the absence of lymphadenitis, and secondary infection.

The problem of etiology has not yet been solved satisfactorily. Attempts at producing the ulcer experimentally by inoculation with the spirilla and fusiform bacilli have failed. The author supposes that these organisms can develop only in a wound which is primarily infected by staphylococci or streptococci.

No specific treatment has been found as yet. The topical application of sulfonamides is ineffective. Penicillin was not available to the author in 1943 but more recent publications reported failure with the use of penicillin. Other antibiotics have not been tried.

The routine treatment consists in dressing with Dakin's solution or 1 per cent formalin, the local application of neoarsphenamin powder, electrocauterization of the borders of the ulcer, and repeated radical curettage of the surface. After the infection has subsided, skin grafts are sometimes necessary. However, in most of the cases it is remarkable how fast epithelization and scarring proceed after the infection has cleared up.

WERNER M. SOLMITZ, M D

EXPERIMENTAL SURGERY

Comparison of the Efficacy of Therapeutic Agents in the Treatment of Experimentally Induced Diffuse Peritonitis of Intestinal Origin SANFORD ROTHENBERG, HENRY SILVANI, SPENCER CHESTER, HELEN WARMER, and H. J. MCCORKLE *Ann Surg*, 1948, 128: 1148

Fulminating diffuse peritonitis was produced in 93 dogs by dividing the vascular supply to the appendix, ligating the base, and crushing the appendix. The omentum and spleen were removed. Twenty untreated control animals died with acute diffuse peritonitis from bacterial infection with intestinal organisms. The average survival period was 39 hours.

Sulfonamide therapy with (1) intravenous sodium sulfadiazine, (2) intraperitoneal sulfasuxidine, (3) combined intraperitoneal sulfanilamide and intravenous sodium sulfadiazine apparently had no beneficial effect. All died with peritonitis similar to that observed in the control animals. However, the survival period in the sulfanilamide-sulfadiazine group was prolonged to 80 hours.

Streptomycin therapy given intramuscularly or intraperitoneally apparently prolonged the survival period of dogs with experimental appendiceal peritonitis to averages of 75 to 92 hours in 14 out of 15 dogs. One animal survived. However, doses of streptomycin that effectively controlled the organisms in the peritoneal cavity caused death from the toxic effect of streptomycin (apparently on the medullary respiratory center).

Commercially available penicillin given intramuscularly at four-hour intervals daily in doses of 100,000 units, 200,000 units, 500,000 units, and 500,000 units, combined with streptomycin, 24 gm, was definitely beneficial in the treatment of experimental appendiceal peritonitis. All animals receiving 500,000 units of penicillin daily survived.

Penicillin containing 15 to 25 per cent penicillin-x in doses of 100,000 units daily, intramuscularly or intraperitoneally, was effective in the treatment of experimental appendiceal peritonitis. Nine of 10 animals treated intramuscularly, and 2 of 5 animals treated intraperitoneally with penicillin-x recovered.

SURFACE-CHROMICIZING*

When gut is chromicized after strands are spun and dried, chrome concentration is very high in surface layers and relatively low in the core. Inner core is digested rapidly—the highly chromicized periphery survives for prolonged periods

ETHICON TRU-CHROMICIZING

Individual ribbons of gut are soaked in chrome bath before they are spun into strand, permitting uniform deposition of chrome. The strand thus has the same chrome content from periphery to center

Why you get a better suture

WITH ETHICON'S TRU-CHROMICIZING PROCESS

The fate of the absorbable suture after implantation and wound closure, and its reactions in the host, are the ultimate test of the suture's quality and dependability.

Today chromicized gut is widely used because of its resistance to digestion until healing is accomplished. In this aspect, the chromic suture must possess these attributes:

1 Sufficient chrome content to withstand premature digestion

2 Chrome concentration must not be so excessive that fragments of the suture resist digestion and persist in tissue. This condition frequently leads to knot extrusion.

In order to obtain a product having the highest possible degree of uniformity, Ethicon chromicizes raw gut strands in the ribbon stage. This more meticulous process was named Tru-chromicizing. The alternative method, used by others, called surface-chromicizing, involves the dipping

of the finished spun and dried suture strand in a chrome bath. These are the results of the two methods:

Surface Chromicizing

In enzyme solution the core of most surface-chromicized gut digests readily, leaving a hollow cylinder which separates into ribbons.

This cylinder may be excessively resistant to enzyme action and remain as an undigested foreign body indefinitely.

Tru Chromicizing

Ethicon Tru chromicized gut exhibits uniform enzyme resistance throughout digestion. It digests from the surface inward and retains its integrity as a unified suture until digestion approaches completion.

Total digestion eliminates the danger of knot extrusions and sterile stitch abscesses.

What Tru Chromicizing Means To You

- 1 Less interference with healing through minimized foreign body reaction
- 2 High tensile strength of suture retained for the healing period, followed by complete absorption
- 3 Uniformity in those physical and physiologic characteristics essential to accurate surgical technique

**To illustrate this comparison, small laboratory trays are used. In commercial production, surface-chromicizing is done under tension. Both processes are performed in large vats.*

UNILATERAL PREFRONTAL LOBOTOMY FOR THE RELIEF OF INTRACTABLE PAIN AND TERMINA- TION OF NARCOTIC ADDICTION

JOHN E. SCARFF, M.D., F.A.C.S., New York, New York

IN 1943, Freeman and Watts observed that patients on whom they had performed bilateral prefrontal lobotomy for the relief of psychotic behavior appeared not to suffer somatic pain to the degree normally expected. Subsequently they electively performed bilateral lobotomy in a group of patients without psychotic disturbances, with relief of somatic pain (1, 9, 10).

Bilateral prefrontal lobotomy, however, because of undesirable effects on intellect and personality, could not be generally applied to the relief of pain due to less lethal though incapacitating disorders.

Since the pain-relieving mechanism of prefrontal lobotomy was not understood, it occurred to me that a unilateral procedure might be as effective as the bilateral one. It was my expectation that a unilateral procedure would not affect intellect and personality adversely, since removal of an entire frontal lobe, when necessary for the removal of a tumor, had been found to have only negligible effect (2, 4, 8). In January of 1948, I performed my first unilateral prefrontal lobotomy. In March, I reported in the *Journal of Neurosurgery* (5) 3 cases in which the unilateral procedure had

been performed, with relief of ipsilateral pain in one case, contralateral pain in the second, and bilateral pain in the third. It was observed even then that abrupt termination of the narcotics on which these patients had become dependent prior to operation was followed postoperatively by none of the customary withdrawal symptoms or signs.

In June of 1948, I reported at the annual meeting of the American Neurological Association a series of 10 cases in which unilateral prefrontal lobotomy had been performed for relief of intractable pain (7).

In the recently published *Proceedings of the Association for Research in Nervous and Mental Diseases*, Koskoff, Dennis, Lazovik, and Wheeler in a paper on the psychological effects of prefrontal lobotomy for the relief of pain, report among other cases 2 in which unilateral lobotomy had been performed in August, 1947, with success. They suggested that unilateral lobotomy be tried before the bilateral operation in patients suffering from neoplastic malignancies (3).

My present paper reports 33 cases of unilateral prefrontal lobotomy performed by me for the relief of pain. These are consecutive cases without omission, beginning in January, 1948, and ending in mid-November. The follow-up periods range from 1 month to 10 months.

From the Department of Neurological Surgery, College of Physicians and Surgeons, Columbia University, and the Service of Neurological Surgery, Neurological Institute of New York, Columbia Presbyterian Medical Center, and the Veterans Administration Hospital, the Bronx, New York.

results in relief of pain were good in 66 per cent, fair in 18 per cent, and poor in 15 per cent.

Establishment of rigid criteria for these series presents a problem for the conscious investigator. When is a result "good," when is it "fair," and when is it "poor"? In the very beginning I set up arbitrary standards as follows: "Good" meant that the patient never voluntarily complained and required no narcotics after the operation. "Fair" meant that the patient continued to complain of some pain after operation but required far less medication to be comfortable. "Poor" meant that he had the same degree of pain and required the same amount of narcotic after operation as before. Twenty-two of the 33 patients have met the criteria set for a good result. Their preoperative pain arose from a variety of pathological processes widely distributed throughout the body, including carcinoma of the breast, carcinoma of the jaw, trigeminal neuralgia, atypical facial pain, aneurysm of the thoracic aorta, carcinoma of the pancreas, carcinoma of the bladder, metastatic carcinoma of the long bones, metastases to spine and pelvis, neuritis of the cauda equina, and advanced arthritis (Table I). The results in these 22 cases were 66 per cent of the series have been completely satisfactory. These patients include those with the longest follow-up periods, the average being $2\frac{1}{2}$ months. One case has followed 5 months, 1 for 8 months, and 1 for 10 months.

Two patients, or 15 per cent of the series, had completely poor results (Table III). The pathological processes and their sites are just listed in this group as in the group with good results. They include sarcoma of the skull, meningioma, or sulcus tumor of the lung, metastatic carcinoma of the spine, idiopathic hemicephalalgia, and palindromic rheumatism.

The most conspicuous failure occurred with meningioma of the skull, or Schminke's tumor. It wonders whether the unique anatomical features present in this case and not encountered in any of the others, notably stripping of the dura, were responsible for this failure. Not only was the unilateral lobotomy unsuccessful in this patient but a

subsequent lobotomy on the second side failed equally to give relief.

A second type of failure is illustrated by the case of a young man suffering intense pain in the left side of the head associated with a rapidly developing third nerve palsy on that side. In addition, he also complained of a somewhat lesser pain in the distribution of the left cervical plexus. Unilateral lobotomy on this man stopped the intracranial pain but had no effect on the cervical pain. The latter was subsequently entirely relieved by laminectomy and posterior rhizotomy. The reason why the lobotomy relieved the severe intracranial pain but failed to relieve the lesser cervical pain remains unexplained. This is the only case in which a patient with more than one pain was not relieved of all pains equally.

In both of the cases cited, nonrelief of pain was immediate after operation. In the other 3 patients of the "poor" group, immediate relief was later followed by return of pain.

Mrs. A. was a woman suffering intense pain from metastases to the cervical spine from a mammary carcinoma, who was completely relieved by a unilateral prefrontal lobotomy. Bedridden by pain before operation, after operation she left her bed, attended church, and enjoyed a quiet round of activities. Six weeks later fresh metastases to the pleura initiated violent paroxysms of coughing, which induced collapse of the cervical spine. With these new developments, pain again appeared in its original distribution, although much less severe than before the unilateral lobotomy.

Another of the patients with result classified as poor had return of pain after a period of complete relief. This paralleled an increasing compression of spinal roots by a superior sulcus tumor of the lung. These 2 cases bring up one of the major questions regarding the efficacy of unilateral lobotomy: Is the late return of pain due to a gradual "fatigue" of the effectiveness of the lobotomy? Or is the return due to progress of the disease with an increase of pain beyond the point where the barrier imposed by the operation is effective? It is my own feeling that one should regard unilateral lobotomy as introducing a *quantitative* rather than an absolute barrier to the experience of pain, and that if pain increases suf-

Fig 1 Author's technique for performing unilateral prefrontal lobotomy under direct vision A, Relationship of incision and trephine opening to coronal suture B Cortical incision corresponds approximately to coronal suture C, The anterior tip of the lateral ventricle is located with a ventricular needle, and the plane of section established immediately anterior to it D, In the plane of section, the white matter is divided in radial fashion until grey matter is everywhere encountered

ficiently, it may penetrate this barrier to some degree

In 6 patients, I have classified the results as fair (Table II) Although the empirical criteria of partial relief of pain and reduction in medication seem reasonable, it is often difficult to determine whether individual cases meet these standards Here are 2 examples

General B was a staff officer of the Greek Army A year ago, he was struck by a military vehicle

and suffered avulsion of the left brachial plexus He arrived in this country 4 months later, complaining bitterly of pain in his denervated extremity, and almost a complete invalid from his reaction to the pain He was observed for several weeks in the hospital before lobotomy was performed During that time, he could be interested in no subject other than his pain He lay in bed moaning and groaning, and all efforts to divert his thoughts from himself were futile Yet the very morning after unilateral lobotomy, this patient demanded that the daily papers be translated for him A few days later, he initiated plans for

flying his children out of Greece and saw that the plans were effectively carried out. He began a vigorous correspondence with his fellow officers in Greece regarding the war. He left the hospital to make patriotic speeches. He visited relatives in the middle west. Finally he secured passage on a plane and returned to Greece, where he resumed his former position in the War Ministry. His wife wrote in November as follows: "The General is much better, very calm, reads hours at a time without complaining of his ailment." A few days later, the General himself wrote "It is impossible for me to bear up. My misfortune is great. I doubt whether anyone else has suffered and is suffering as much as I without any improvement."

How shall we classify this patient? By his own protestations, he is a complete failure. By the account of his wife, and in the light of his activities, he has been vastly improved by his operation. He was classified as fair.

Mr A is a 56 year old employee of the city of New York and works as a legal clerk in the tax division of the department of finance. He has a superior sulcus tumor of the left lung, at present so extensive that it presents as a huge mass in the supraclavicular triangle. He has complete paralysis of all the muscles of the left hand, which is now blue and swollen, and a partial paralysis of many other muscles of the upper extremity. Before lobotomy, this man was a bed patient at the Presbyterian Hospital for 3 weeks because of pain. Since operation, he has returned to his job, working a full 8 hour day, and functioning as efficiently as before operation. Yet this man, with a smiling face tells me that his pain is worse than it was before the operation.

How is he to be classified? An independent study of him recently made by Dr James Cattell of the Psychiatric Institute states "The pain has been definitely diminished by the operation in view of his present performance."

and his emotional state as objectively viewed ” I have therefore classified him as fair

As will be seen from these cases, there is difficulty in evaluating the results in patients who, after operation, still complain of pain but act as if they did not have it

Effort has been made to determine factors responsible for good or bad results In my earlier series of 10 cases reported in June, it was pointed out that failures to relieve pain had occurred only in those cases in which the lobotomy had been performed on the side of the brain contralateral to the somatic pain, and on the nondominant hemisphere Although it was recognized that the series was too short to justify any firm conclusions, it was thought that these observations might subsequently lead to significant deductions As the series has increased, however, these earlier observations have not been confirmed At present there is no evidence establishing the superiority of the ipsilateral lobotomy, or of lobotomy on the dominant hemisphere

A standard technique has been employed in all 33 procedures The lobotomy has been

performed under direct vision, in a plane passing just anterior to the tip of the lateral ventricle, and carried laterally, medially, and ventrally until grey matter is everywhere encountered (6) (Fig 1) If pain is to be relieved by unilateral lobotomy, the lobotomy must be thorough, and this can be accomplished only under direct vision If performed in this manner, the operation produces amazingly little shock Many of the patients have been out of bed on the day following operation, and almost all of them by the end of the third postoperative day Unilateral lobotomy can be safely applied to persons who could not tolerate more difficult technical procedures such as high cervical cordotomy, medullary tractotomy, section of multiple cranial nerves, or mesencephalic tractotomy

EFFECT ON INTELLECT AND PERSONALITY

If unilateral prefrontal lobotomy is to prove a better procedure for the relief of intractable pain than the bilateral operation, it must not only relieve pain, but it must do this without the undesirable effects on intellect and per-

sonality which often accompany the bilateral operation. Postoperative evaluation of the patients in this series has established the fact that unilateral lobotomy characteristically produces no significant alteration in intellect or personality.

Of the 33 patients operated upon, 15 received standard psychometric evaluations both before and after operation. In addition, 9 other patients unable to be tested before operation because of pain received postoperative evaluations. Nine patients were not tested. Only 1 of the 24 receiving postoperative testing had a score as low as "borderline", unfortunately, this patient was one of those whose preoperative suffering was so great that preoperative tests could not be given. On the other hand, 5 patients scored "superior" after operation, and 2 scored "very superior".

Chief interest, of course, lies in the patients who had standard psychometric testing both before and after operation. Of these 15, 11 had no significant differences between their preoperative and postoperative scores. Four showed falls in score, ranging from 13 to 23 points. In each of these, however, there were factors other than the operation which might well have contributed to the lowered score. One of the patients was in the terminal stage of carcinomatosis by the time postoperative testing was done. Another had advancing cerebral metastases, and the 2 remaining had showed strong psychotic tendencies prior to operation.

Of the 15 patients having both preoperative and postoperative psychometrics, there were 6 who had tests done shortly after operation, and then had repeat testing several weeks later. It is of prime significance that every 1 of these 6 patients' second postoperative test showed a substantial gain in score over his first postoperative test. The gains ranged from 10 to 23 points. One of these repeat-test patients was Case 31, a young woman who dropped from a preoperative score of 122 to 107 immediately after operation. However, when tested a second time, 3 weeks after the first postoperative test, her score was 126. This score represents not only a recovery of the lost 15 points, but a gain of 4 points over her preoperative psychometric level. These observations

mean that the patient's intellectual condition after operation is not a static one but a progressively improving one.

An effort was made to determine in what principal categories of intellectual activity significant changes took place following operation. The categories of greatest interest, because of their general acceptance as indices of adult intelligence, are retention of old learning, capacity for new learning, arithmetical reasoning, and social adjustment. On analysis of the 15 patients with preoperative and postoperative testing, we find no characteristic constancy in the categories affected, or in the direction in which they were affected. The retention of old learning was unchanged in any patient. In rate of new learning, there was marked increase in 2 of the patients, moderate increase in 2 others, slight increase in 1, no change in 2, slight decrease in 1, and moderate decrease in 2. Wherever changes were recorded in ability for mathematical reasoning, there was improvement. Only 1 of the 15 patients showed any decrease in social adjustment as evidenced by the Rorschach test. The only conclusion which can logically be drawn from this analysis is that there is no characteristic improvement or impairment in any field of intellectual activity following unilateral prefrontal lobotomy.

Quite apart from these formal scorings, but of no little importance in evaluating the results of this operation, are the opinions of the patient's personality expressed by his friends and relatives after operation. In not a single instance has the comment been made that the patient's personality has suffered. Indeed, in several instances, the family and friends have expressed pleasure over the striking improvement in the patient's general social outlook after operation.

The inevitable conclusion is that the only postoperative change in personality is the change which anyone would experience from being relieved of intolerable pain.

TERMINATION OF DRUG ADDICTION

The effect of unilateral prefrontal lobotomy on the termination of drug addiction was entirely unforeseen. It certainly was not a primary objective of the operation, indeed it was

my expectation that patients who no longer needed narcotics to relieve pain after operation would still need them to forestall withdrawal symptoms. However, experience with 15 patients of this series who were addicted to the use of drugs in varying degrees because of pain has shown that unilateral lobotomy permits withdrawal of narcotics without withdrawal symptoms.

The first patient heavily addicted to narcotics operated upon was Mrs. R. When admitted to the Neurological Institute in August, 1948, Mrs. R. already had extensive carcinomatosis involving liver, bile ducts, and pancreas. For many months prior to operation, she had been receiving $3\frac{1}{8}$ grains of morphine, plus $\frac{1}{4}$ grain of dilaudid, every 3 hours. Within 48 hours after unilateral lobotomy, her entire narcotic intake had been reduced to $\frac{1}{2}$ grain of morphine, every 3 hours. This was accompanied by none of the symptoms and signs usually associated with abrupt reduction of the drug. A note written on the third postoperative day by Dr. Rollo Masselink, attending neurologist, reads as follows: "The patient was lying quietly in bed in no apparent distress. There was no evidence of increased perspiration or increased pulse rate, no agitation. When asked if she needed sedative, she replied, 'No, I have a little pain, but it doesn't bother me any'." A letter from her family physician, Dr. Robert S. Ackerv, written 2 months after her operation, reads as follows: "The patient has no pain. She now receives $\frac{1}{8}$ grain of morphine every 3 or 4 hours, and sometimes only bellergal or sterile hypos. I allow her the comfort of such small doses in view of the advance of the carcinoma." This means that the patient's narcotic intake of 25 grains of morphine, plus an equivalent amount of dilaudid, per day has been reduced to $\frac{3}{4}$ grain of morphine per day, with the dilaudid entirely stopped.

Another patient, Miss D., was admitted to the Neurological Institute in September, suffering severe pain from metastatic carcinoma to the cervical spine. For many months prior to admission here, she had been receiving 3 grains of morphine, every 3 hours. Immediately following operation, all narcotics were stopped. A note by Dr. E. G. Zabriskie of the neurological service on the seventh postoperative day reads as follows: "Seen today in consultation with Dr. Scarff. The transformation is remarkable. She is complacent, shows no pain, is proud of the fact that she no longer uses narcotics."

A third patient, Mrs. L., was admitted to the Neurological Institute suffering extreme pain in the back from a saccular aneurysm of the thoracic aorta. A letter from Dr. S. G. Loman, her referring physician, states that while she had been under his care at the Englewood Hospital, he had been "unable to control her excruciating pain with hypodermic injections of morphine or demerol." Following unilateral prefrontal lobotomy, all narcotics were

abruptly terminated without any of the customary evidences of withdrawal. During her postoperative period in the hospital, this patient never requested further medication for the relief of pain. A letter from Dr. Loman, dated October 14th, 2 months after her operation, reported that she was bright and cheerful, without pain, and without need of any analgesic medication.

One patient only in the series of 33 cases had postoperative behavior characteristic of narcotic withdrawal. This lasted for 72 hours and then receded.

Fourteen of the 15 patients with termination of drug addiction had a proved organic basis for the pain which necessitated the medication. One woman, however, deserves special mention because no organic basis for her complaints was ever established.

Case 28 had been under treatment for pain in the thoracic spine for 17 years. During this time, she had had numerous hospitalizations and three spinal fusions, none of which had altered significantly her professed pain. From November, 1946, until her admission to the Neurological Institute in September, 1948, she had been taking either dilaudid, $\frac{1}{32}$ grain, or demerol, 100 milligrams every 3 hours. If these medications were delayed for even a short time, the patient became highly agitated.

The most careful examination by myself and by special consultants in related fields at this hospital never revealed an organic basis for her pain, nor any objective manifestation of organic disease.

On October 15th, unilateral prefrontal lobotomy was performed. Since that time, this patient has not only not complained of having pain, she has denied having pain. She has never had a single dose of narcotic or analgesic of any sort, nor has she expressed a desire for drugs during these 2 months. Since no organic basis for pain was ever established, it seems probable that the pain was psychogenic, and the drug addiction a primary one.

The value of unilateral prefrontal lobotomy in terminating drug addiction due to pain seems well established. The last case cited gives promise that the operation may have value also in the termination of primary addiction.

The mechanisms by which pain has been relieved and drug addiction terminated in these cases remain obscure. Certainly at this time they are limited to the realms of speculation, and I let the matter rest there.

SUMMARY

The results of unilateral prefrontal lobotomy performed for the relief of intractable pain

in 33 patients have been good in 66 per cent fair in 18 per cent, and poor in 15 per cent. In 15 patients of this series having careful psychometric evaluations before and after lobotomy, no significant impairment of intellect or personality could be found. In 15 of 16 patients heavily addicted to narcotics because of pain prior to operation abrupt termination of the narcotic has been effected immediately after operation without withdrawal symptoms. One additional patient, appearing to have a primary narcotic addiction, was likewise cured of her dependence on the drug.

These data indicate that unilateral prefrontal lobotomy is both an effective and an acceptable measure for the relief of intractable pain in many conditions where other measures cannot be applied.

ratio was 1.43. The bromsulfalein test showed a 40 per cent concentration of the dye after 5 minutes and a 1 per cent concentration after 30 minutes. The total blood cholesterol was 250 milligrams per cent, the esters were 142 milligrams per cent, and the ester cholesterol ratio was 57 per cent. Roentgenograms of the chest taken at weekly intervals were normal. Microscopic examination of sections of liver stained with hematoxylin and eosin and with osmic acid showed that the capsule was slightly thickened and the liver parenchyma was natural except for a moderate amount of intracellular fat. Occasionally about the portal canals there was a collection of small and large round cells. The bile ducts and sinusoids appeared normal (Fig. 2).

CASE 2. H. K., a white male, aged 49 years, was transferred from the medical service to surgery with a diagnosis of gastrojejunocolic fistula. Fourteen years ago a posterior gastrojejunostomy was performed for duodenal ulcer. About a year ago he developed a severe diarrhea with 10 to 12 daily movements. Weakness became progressively worse and his weight was reduced from 135 pounds to 90 pounds. He had additional signs and symptoms referable to multiple avitaminosis characterized by polyneuritis and cheilosis. The blood protein at the time of transfer averaged 4.4 grams per cent, albumin was 2.8 grams per cent, globulin was 1.6 grams per cent, and the albumin globulin ratio was 1.7. Physically the patient revealed the characteristic signs of prolonged

inanutition with generalized nutritional edema. He was prepared for operation on a regimen of 9 successive daily infusions of the combined fat emulsion. The efficacy of these daily infusions was dramatically apparent, for it played the major role in his daily subsistence since any food taken orally was rapidly lost through the gastrojejuno-colic fistulous route before any nutritional benefits could be derived. The operation was conducted under cyclopropane-oxygen anesthesia. He received 2 blood transfusions during the course of the operation which consisted of the removal of the fistula and the restoration of the continuity of the bowel by means of posterior gastrojejunostomy, jejunojejunostomy and colocolostomy plus a complementary cecostomy. At the time of operation a liver biopsy was taken. The postoperative course was critical during the first week because of a secondary alkalosis due to excessive gastric suction. After restitution of chemical balance the postoperative course was uneventful. Microscopic sections of the liver showed that the capsule and hepatic lobules were of normal architecture. There was a mild lymphocytic collection in the periportal areas. Intracellular fat was present (Fig 3). One month after operation the total blood protein was 6.9 grams per cent and the albumin globulin ratio was 2.3. The alkaline phosphatase was 4.3 King Armstrong units, the blood urea nitrogen was 18.5 grams per cent, cholesterol was 103 milligrams per cent, cholesterol ester was 132 milligrams per cent and the ester cholesterol ratio was 68 per cent. On this date his weight was 127 pounds and all peripheral edema had subsided. All the postoperative roentgenograms of the chest were negative for any pneumonic infiltration. Postoperatively the patient also received the combined

fat emulsion intravenously. In a 24 hour special study period during which 1 liter of the emulsion was infused and no other nutrients permitted, data were obtained for the values of the respiratory quotient, the oxygen uptake, and carbon dioxide output in response to the infusion (Fig 4). Another series of tests showed that the patient was now maintained in positive nitrogen balance whereas previously he was in marked negative balance. Peripheral blood studies revealed that the emulsion had not caused any hemolytic anemia.

Adverse reactions relative to the present series of infusions were 8 per cent in the Group 1 series and 6 per cent in the Group 2 series. Of the reactions, most were of the pyrogenic variety with rapid subsidence of temperature within 24 hours. The most severe reaction was that of the constitutional type manifested by severe cough or nausea and vomiting. The latter occurred usually in patients who were in the advanced stage of inanition with anemia and hypovolemia. To obviate this type of reaction it was first necessary to correct for the anemia and to infuse smaller amounts of the combined emulsion until tolerance for larger volumes was obtained. Patients allergic to amigen were equally sensitive to the combined fat emulsion. Concomitant treatment with pyribenzamine permitted the full administration of the emulsion without interruption as

was demonstrated in Case 4, Group 2 Local phlebitis after multiple infusions did not develop Infiltration of the subcutaneous tissues of the forearm occurred accidentally on 3 occasions Surgical drainage was necessary in 1 patient and in the other 2 the fluid was absorbed from the tissues without slough Fat embolization to lung or brain either produced by the infusion or potentiated at a later date by the anesthetic agent did not occur in the group subjected to surgery

DISCUSSION

In recent years, advances both academic and practical have been made in the knowledge of dietary fat and its role in nutrition Fats have been shown to be of significant importance in phosphorus and calcium utilization, as carriers of fat soluble vitamins and as essential for B vitamin effectivity (vitamin sparing action) In physiology, fat has been proved to affect the secretion of enterogastrome which in turn inhibits gastric motility From the biochemical standpoint newer knowledge has been attained on such phases of fat nutrition as the coefficient of digestibility of natural fats, the pathways of distribution of fat in the body, the role of the phospholipids in fat transport, extrahepatic fat metabolism, the lipotropic effect of protein, the hormone lipocortic and newer theories on the degradation of fatty acids

Classic experiments in nutrition have shown that where fat alone was supplied to the fasting organism little protein was destroyed while in the absence of fat large quantities of endogenous protein were destroyed Nitrogen equilibrium was maintained best when the food intake comprised both protein and fat Quantitatively the ingestion of protein in excess of 3.5 times the amount lost during starvation was required for nitrogen balance but by the addition of fat to the latter the protein requirement was reduced from 3.5 to 1.6 for the restoration of nitrogen equilibrium Bloor found that the ingestion of fat was accompanied by a rise in the concentration of lipids in the blood while Magnus-Levy showed that there was a concomitant increase in heat production above that of basal metabolism Both of the latter values returned to the initial level,

Fig 4 H K, Group 2, Case 2, the respiratory quotients, temperature, and blood pressure in response to an infusion of 1 liter of the 10 per cent combined fat emulsion

the blood fat very rapidly, the increased metabolic rate usually within 10 hours Lusk amplified the latter by showing that the respiratory quotients were altered primarily because of the metabolism of fat plethora In the present studies the biochemical functions of the body after the infusion of the combined fat emulsion were similar to those described after the ingestion of fat The intravenous injection of fat was accompanied by a temporary rise in the blood fat and the chylomicron counts of the blood During the acute phases of the infusion there was an increase in oxygen uptake (metabolic rate) and an alteration of the respiratory quotient Nitrogen equilibrium was more easily attained by use of the combined fat emulsion than could be obtained possibly by forced feedings through a tube or infusions of large volumes of protein hydrolysate and glucose solutions The potential clinical value of intravenous fat emulsion as recognized by

Holt and his coworkers was thus extended for adult use with equal benefits

In earlier studies by others on the effect of the intravenous fat on vital organs pathologic changes ranging from macrophage phagocytosis by mononuclear and foreign body giant cells to noncaseating granulomas were described in the lungs and the livers of experimental animals (1). Recently it was proved that the emulsifying agent particularly the unfractionated phosphatides were causative of such pathology. In the present studies gelatin was used exclusively as the stabilizer because of its proved nontoxic qualities. In no case did the gelatin render the emulsion toxic or interfere with renal function¹. Except for the presence of intracellular fat and the occasional periportal round cell accumulation, no true granuloma or inflammatory reaction was found in the human liver sections. Our previous experience in animal experiments showed that the intracellular fat subsequently disappeared from the liver. Since no lung biopsy sections were obtained, pneumonic infiltration due to fat was checked by means of x-ray films of the chest which were negative. Further, autopsy examination of the lungs of patients from Group 1 failed to demonstrate the presence of any infiltrative lesions in this organ ascribable to the fat which had been administered.

¹The caloric value of the gelatin fraction in the emulsion its contribution to nitrogen equilibrium its part in urinary nitrogen etc. were not calculated in the present studies although Brunschwig has reported some evidence of gelatin utilization.

SUMMARY

1 A series of 22 surgical patients were treated by intravenous infusions of a 10 per cent combined fat emulsion replacing solutions of protein hydrolysate and glucose.

2 Observations were made as to reactions caused by the emulsion and its possible effects on the liver and lung. The incidence of toxic effects encountered was sufficiently low to recommend its use for human patients.

3 Four detailed case studies were reported on the effect of the combined fat emulsion on metabolism and its role in support of nitrogen equilibrium.

4 The intravenous use of the combined fat emulsion appeared to be of definite advantage as a therapeutic adjuvant in partial and in major parenteral alimentation.

NOTE.—Since this report was submitted for publication a total of 100 patients have received infusions of the combined fat emulsion. Our studies were extended to the use of 15 and 20 per cent combined fat emulsions infused intravenously into human subjects. Deuterized fat homogenized with the present emulsion provided additional evidence of metabolic utilization of intravenous fat.

DIAGNOSIS OF PREINVASIVE CARCINOMA OF THE CERVIX

JOSEPH SKAPIER, M D , New York, New York

DIAGNOSIS of early preinvasive carcinoma of the cervix has become more and more frequent.

While a decade ago this type of cancer was seldom reported in the literature and was considered a rare type of malignant growth of the female genital tract, more recently preinvasive carcinoma of the cervix is a very common finding. This type of early cancer is most often detected in cancer prevention clinics during routine periodic pelvic examinations of assumingly healthy asymptomatic young women (7, 12, 13). In most of these cases pelvic examination reveals benign lesions or no lesions at all. The detection of early preinvasive carcinoma of the cervix and its control are due to the recent advances in methods of the detection of cancer in the female genital tract, such as the vaginal smear method or the performance of routine cervical biopsies or both (5).

While the biopsy still remains the only method of diagnosis of invasive carcinoma of the cervix if the biopsy forceps is able to remove a fragment of the visible lesion, the routine vaginal smear is the method for diagnosis of preinvasive carcinoma of the cervix when there is no suspicious lesion accessible for biopsy.

The material for this study was taken from the Strang Cancer Prevention Clinic of Memorial Hospital during the last 2 years. Some of the cases of preinvasive carcinoma reported in Table I were diagnosed by Dr E. Jones who was in charge of the laboratories of cytology until 1947.

The term preinvasive carcinoma which denotes a neoplastic lesion confined to the epithelium without infiltration beyond the basal membrane is also termed intraepithelial carcinoma or carcinoma *in situ*.

This type of cancer was chiefly described by Rubin, Meyer, and Broders, and more recently by Pund, Te Linde, and Foote and Stewart (5). Their studies emphasize methods of detection and treatment of preinvasive carcinoma of the cervix, and also emphasize the morphologic changes of the squamous epithelium as seen in tissue sections.

DISCUSSION

The technique of collecting vaginal fluid and the staining procedure used in our clinic are those introduced and recommended by Papanicolaou. We also employ Papanicolaou's classification (12, 13) of smears as applied to the diagnosis of malignant cells, namely, those smears classified as I are negative, those as Class II are also negative for malignancy but show cells of benign lesions such as vaginitis, cervicitis, polyp, etc., those as Class III show cells with abnormal features and suggestive of malignancy, those as Classes IV and V are fairly conclusive or conclusive for malignancy. This classification has been used in our laboratory since 1947. Cases reported in Table I up to 1947 were classified as negative, suspicious, or positive.

Among the 10,000 new female patients seen in our clinic during the past 2 years, 30 cases of cancer of the cervix were detected. These 30 cases include invasive as well as preinvasive carcinomas of the cervix. In 28 of these 30 cases the diagnosis was first made by vaginal smears and consequently confirmed by biopsy. Of these 30 cases of carcinoma of the cervix, 21 cases (70 per cent) were of the early preinvasive type and 9 of the invasive type. Until 1948, 3 cases of carcinoma of the cervix, 2 of the preinvasive and 1 of the invasive type, were detected among 1,000 assumingly healthy, asymptomatic females examined in our clinic (12, 13). Among the 2,000 new patients examined during the first 6 months of 1948, 6 cases of preinvasive carcinoma were detected and 2 cases of the invasive type, which shows

*In none of these cases was carcinoma suspected clinically

†Until January 1947 reports were given as negative, positive or suspicious. Later on the Papanicolaou classification was applied.

‡Diagnosis of the biopsies was made in the laboratory of pathology of Memorial Hospital.

Fig 1 Isolated malignant cell of a case of intraepithelial carcinoma of the cervix

Fig 2 Isolated cells of intraepithelial carcinoma of the cervix

an increase in the percentage of detected pre-invasive as well as of invasive cancers of the cervix in our clinic. Thus, 4 cases of carcinoma of the cervix, 3 of the preinvasive type and 1 of the invasive type, were detected among each 1,000 asymptomatic patients examined in our prevention clinic since January 1948 in contrast with the 3 cases per 1,000 patients detected during 1946 and 1947. In addition there are 5 more cases in which repeated vaginal smears were reported as highly suspicious or positive (Classes III and IV) for preinvasive carcinoma of the cervix during 1948 without a confirmatory biopsy up to present time. Further exploration, such as repeated biopsies, is advised in these 5 cases.¹

Table I enumerates the 21 cases of preinvasive carcinoma of the cervix all of which were confirmed by biopsy. All 21 patients were asymptomatic in relation to the female genital tract, and the pelvic findings as recorded in the clinical charts were apparently those of benign lesions. However, in 8 cases of the 21, biopsies were taken at the same time as the vaginal smears. Biopsy was performed not because malignancy was suspected, but because the lesions seemed to be more extensive or presented somewhat atypical appearance, such as granular erosion with laceration or contact bleeding. Consequently, in all the

remaining cases biopsies were performed on account of positive or suspicious smears. There were 2 false negative smears (Cases 1 and 13) among the 21 cases of preinvasive carcinomas (10 per cent). In these 2 cases the smears were negative while the biopsies were positive for preinvasive carcinomas. Subsequent smears were reported as positive. This demonstrated that a single negative smear does not always rule out cancer of the female genital tract.

The lapse of time between the first positive or suspicious smear and the positive biopsy is very significant. In 3 cases (Cases 2, 11, 19) smears were reported as positive 1 to 3 years prior to the positive biopsy for preinvasive carcinoma, in 3 other cases (Cases 7, 10, 14) the interval was from 3 to 9 months. Repeated exploration of the cervix and endocervix of a patient showing positive or suspicious smears was done until a positive biopsy was obtained. Whether therapy should be given after failure by a biopsy to confirm the positive cytologic report is still debatable.

In Cases 3 and 4 positive smears and biopsies were demonstrated in 1946, but subsequent smears and biopsies have given negative results. The explanation may be that the small preinvasive cancerous foci were removed entirely by the biopsy forceps and that there has been no relapse or metastases up to present time.

The ages of the patients with preinvasive carcinoma of the cervix range from 35 to 56

¹Three cases of these 5 which were reported as positive were recently confirmed by biopsies as carcinomas *in situ*. The other 2 cases which were reported as suspicious have not as yet been confirmed by biopsies.

Fig 3 Cells found in cases of intraepithelial carcinoma of cervix

Fig 4 Cluster form of malignant cells of intraepithelial carcinoma of the cervix

years. It is of some interest to note that of the 21 patients with preinvasive carcinoma of the cervix, 7 (33 per cent) were Jewish. This point is stressed because of the numerous reports that carcinoma of the cervix is extremely rare among Jewish women.

CRITERIA OF MALIGNANCY OF PREINVASIVE CARCINOMA OF THE CERVIX

Vaginal smears of invasive carcinomas show malignant cells with specific cellular charac-

teristics of malignancy. The criteria of the malignant cell of invasive carcinoma were first described by Papanicolaou and then by other authors.

Vaginal smears of preinvasive carcinomas show malignant cells with certain cellular characteristics highly suggestive of early non-invasive carcinoma of the cervix.

Smears of preinvasive carcinoma of the female genital tract reveal the following types of exfoliated cells: (1) malignant cells suggestive

Fig 5 Normal superficial epithelial cells showing normal nuclei

Fig 6 Superficial epithelial cells showing nuclear abnormalities

of preinvasive carcinoma, (2) cells with some malignant potentialities, (3) cells of an inflammatory type

Malignant cells of the squamous type are present either in isolated or in cluster forms. There are two types of isolated cells suggestive of preinvasive carcinoma. The first type of cells originates from the deeper basal layer. They are rather small in size. The nuclear shape varies from round to oval and with a thickened nuclear membrane. The nucleus is prominent, hyperchromatic, and large in proportion to the cytoplasm. The nucleoli are prominent, large, and the cytoplasm is present in the form of a small and thin rim. The cytoplasmic borders are indistinct and hazy (Figs 1 and 2).

Another type of isolated malignant cell suggestive of preinvasive carcinoma of the cervix may also be seen in the smears. In this second type of cells the nuclear cytoplasmic ratio is well preserved, the cytoplasm appears acidophilic with irregular edges. The nucleus is bizarre shaped, irregularly outlined, and may appear to be one dark grayish mass or to have a dark granular content. The nucleolus is indistinct. This second type of cell also originates from the deeper basal layer (Fig 3).

Both types of cells may be found in the same smear. Whether one type of cell is a stage of transformation to the other type is difficult to ascertain. These two types of malignant cells may also be found in cluster forms. Loss of cellular pattern and overcrowding of these abnormal cells are the characteristic features for the cluster form (Fig 4).

Frequently smears containing these cells suggestive of preinvasive carcinoma of the cervix contain also cells originating from the superficial epithelial layer. These superficial cells have a normal cytoplasm but show nuclear changes of quite a suspicious character, such as hyperchromatism, enlargement, etc. The presence of these abnormal superficial cells alone without the presence of abnormal cells of the deeper layers may also reveal carcinoma *in situ* in about 50 per cent of such cases (Figs 5 and 6).

Smears of preinvasive carcinoma of the cervix show quite frequently inflammatory type of cells, such as clusters of polymor-

phonuclears, red blood cells, basal cells having a halo around the nucleus or marked vacuolization of the cytoplasm. This is due to the fact that a benign inflammatory lesion is associated with the preinvasive cancer or the preinvasive cancerous focus itself is secondarily infected. In the absence of a secondary infection of the preinvasive cancerous focus or of a benign inflammatory lesion there is no inflammatory type of cells demonstrated in the smears.

Thus in the cytology of preinvasive carcinoma the pathologic findings in smears usually corroborate those in tissue sections. Nevertheless characteristics of cellular malignancy of invasive or noninvasive type can quite often be better demonstrated in smears from the isolated cells rather than from tissue sections. Strikingly enough the exfoliated malignant cells in preinvasive cancer are detected prior to the appearance of a visible malignant focus.

The vaginal smear method is an efficient and reliable test for the detection of preinvasive carcinoma of the cervix. This method of screening in cancer prevention clinics is simple, and the degree of accuracy of course depends on the care with which the smears are taken, the time given for the reading of each slide, and the training and experience of the cytologist. The great advantage of this method is primarily that we are able to discover the preinvasive type of cancer of the cervix earlier than would otherwise be done. In our series most of the patients would have been treated at a much later date if the vaginal smear had not been used as a screening method.

Various recent publications and editorials (3, 4) gave different statistical data on the percentage of detected preinvasive carcinomas of the cervix by this screening method and also emphasized the high cost of this test (3). We believe that 10 minutes of reading of the vaginal and cervical smears of each case is quite sufficient and that the elimination of all "not negative" smears (Classes III to V) should be done by a well trained cytologist in centralized laboratories. The cost of such a procedure will certainly be much lower than that given by certain authors in their recent publications.

We believe that detection of 3 to 4 cases of early preinvasive carcinoma of the cervix by this method among 1,000 assumingly healthy females is quite an encouraging result

Our experience indicates that the accuracy of this test depends upon remembering the following. Each smear must contain vaginal and cervical fluids. A single negative smear does not mean that the patient is free of cancer since 10 per cent of such smears may be expected to be falsely negative. It is always desirable to confirm the positive or suspicious smear first by other smears and subsequently by biopsy.

SUMMARY

Clinical and cytological studies of 21 cases of preinvasive carcinoma of the cervix are presented. These cases were detected in apparently healthy asymptomatic female patients by means of the vaginal smear method.

The study consists of a clinical analysis of the findings in 21 cases based on the age of the

patient, race, examination of the pelvis, and time interval between the positive vaginal smear and the confirmatory biopsy.

The criteria of malignancy of the exfoliated cell of preinvasive carcinoma seen in the vaginal smear are discussed.

VESICOINTESTINAL FISTULAS

JOHN K ORMOND, M D, F A C S, JOHN W BEST, M D,
MILTON E KLINGER, M D, Detroit, Michigan

PRAXAGORAS described the first case of vesicointestinal fistula in the second century. In the nineteenth century Cripps placed the entity on a firm footing with his treatise on "The Passage of Air and Feces Through the Urethra." Since then the attention of both general surgeons and urologists has been attracted by this interesting lesion and to date in the neighborhood of 700 cases have been formally recorded in the literature. In the past two decades the most exhaustive review is that of Kellogg bringing the literature up to date to 1936 and including a detailed analysis of 37 cases, reported by others between 1925 and 1936. Since then additional reviews and case reports have appeared by Higgins, Winsbury-White, Reagen, Ferner, Rusche and Bacon, Mayo and Miller, Peters, Barnes and Hill, Lazarus and Marks, Ewell and Jackson. It is evident from these studies that vesicointestinal fistulas fall into four general classes from the etiological standpoint, namely congenital, traumatic, neoplastic, and inflammatory.

Table I gives the statistics of several recent series, including our own.

Inflammatory and neoplastic fistulas comprise more than two-thirds of the reported cases and many more of the inflammatory type have been reported than of the neoplastic. However, it must be pointed out that the quoted statistics are misleading. Sutton's series, for example, includes only vesicosigmoidal fistulas which had been operated on, while other series include all types of vesicointestinal fistulas. Single case reports are very apt to be of the inflammatory type, and fistulas resulting from carcinoma are not thought of sufficient interest to report. Hence, a long series of reported cases is much less likely to give a true picture of the relative frequency of the various types than are the much shorter

From the Henry Ford Hospital

series seen by single individuals or groups, such as the Higgins Cleveland Clinic series or Ewell's or ours. These latter all show carcinomatous fistulas to be the most numerous, followed by inflammatory fistulas, with the other two types trailing far behind.

This report is based on 25 cases of vesicointestinal fistulas seen at Henry Ford Hospital. Among these were no congenital cases, 3 were traumatic, 14 neoplastic, and 8 inflammatory in origin. The sex distribution indicated a predominance of men, there being 18 males and 7 females. Thirteen of the fistulas were rectovesical, 11 sigmoidovesical, and one ileovesical.

The condition was most common in the middle and older age groups because of the higher incidence of neoplasms and diverticulitis of the colon in these people. In our series the youngest patient was 30 years of age, the lesion in this case being secondary to diverticulitis of the sigmoid and the oldest patient was 73, the fistula having followed a radical perineal prostatectomy for carcinoma. The average of the entire series was 50.2 years.

THE DIAGNOSIS

The symptomatology upon which a presumptive diagnosis is frequently made usually includes one or another of the following: pneumaturia, the passage of fecal material and particles of food with the urine, and the passage of urine through the bowel. Other symptoms which occur with some regularity are those of vesical irritability. Not infrequently such symptoms as burning, frequency, and painful urination may antedate the actual formation of the fistula, and in the absence of other suggestive symptoms, may be misleading for long periods of time. Lazarus and Marks have pointed out that such symptoms may exist in the "prefistula" or "incipient fistula" stage particularly when the inciting

TABLE 1—STATISTICS OF RECENT SERIES

lesion is primary in the bowel. One patient in our series presented just such a picture and is worth presenting in some detail.

CASE REPORT

The patient was a 53 year old man who had symptoms of frequent painful urination and a persistent pyuria with a small bladder capacity. The symptoms had been present for over 10 years. There had never been any pneumaturia, passage of urine from the bowel or fecal material in the urine. Cystograms showed no fistulous tract. Cystoscopy showed no sign of a fistulous opening. His was considered to be a case of interstitial cystitis and so treated with little benefit. At one time he was admitted with a perforated sigmoid and peritonitis which he successfully weathered with the help of a transverse colostomy. During this time the urinary symptoms subsided only to recur when the colostomy was closed. At that time a barium enema showed multiple diverticula of the sigmoid and descending colon. A transverse colostomy was again performed and during a subsequent operation, when the rectum and sigmoid were resected, a distinct fistulous connection between the sigmoid and bladder was found.

The combination of persistent bladder and lower bowel symptoms should always call for exhaustive studies to rule out the existence of a fistula.

Conversely, the onset may be sudden and explosive in its nature as illustrated by another patient in this series. He was a man of 49 who had been treated for mild gastrointestinal symptoms unassociated with urinary disturbances or pyuria. Suddenly he began to void considerable amounts of gas and fecal material in the urine. Further study and operation showed a carcinoma of the sigmoid which had extended into the bladder wall and ulcerated through the mucosa.

Symptoms may also include lower abdominal discomfort and rectal pain referable to the inflammatory or neoplastic changes taking place in the bowel or peritoneal cavity.

The actual presence of the fistula and its precise location are often difficult to demonstrate. Cystoscopy, cystogram, barium enema, proctoscopy, instillation of dyes into the rectum and bladder, and biopsy of suspicious areas are commonly utilized. Equally commonly they fail to provide a satisfactory answer. Barnes and Hill point out, in their series of 14 cases, that cystoscopy showed changes in 13 but in only 2 could the fistulous opening actually be seen, in 11 cystograms the fistula was demonstrated in only 3, and of 6 barium enemas none showed the tract. This is in general agreement with our own findings. In cases secondary to diverticulitis the barium enema will often show the bowel changes even though the actual fistula itself may not be apparent. In conjunction with the symptoms, however, these findings are an important clue in this group of cases. Occasionally all the diagnostic studies are fruitless and recourse must be had to surgical exploration, as illustrated by the first case quoted above.

CONGENITAL FISTULAS

Congenital fistulas are rare lesions and none were encountered in our series. When they occur there is almost invariably an associated congenital imperforate anus. Early colostomy and subsequent attempts at perineal plastic procedures with excision of the fistula and possibly cystostomy are recommended as the most logical sequence.

TRAUMATIC FISTULAS

Three cases, all rectovesical, in this series resulted from trauma. In general, traumatic causes of fistula are not common, as emphasized by Higgins. In a survey, by Robinson, Culp, and associates, of injuries to the genito-urinary tract in the European theater during the recent war, it was pointed out that of a group of 100 perforating lesions of the bladder in 64 of which there were associated injuries to the bowel only a single case of fistula was found. In recent years surgery has become more prominent as a cause of this lesion. Two of our cases were incident to prostatic operations, both for carcinoma. The other followed a severe fracture of the pelvis. Other causes usually cited are penetrating wounds, instru-

mental delivery, ingested foreign bodies such as toothpicks, pins, and bone fragments, foreign bodies left in the peritoneal cavity during operations, vesical calculi, x-ray and radium. The inclusion of the latter in this group when they have been used to treat neoplasms may be open to question unless one can demonstrate microscopically that no evidence of tumor cells remains. The cases in our series related to x-ray or radium therapy have been included in the neoplastic group. The diagnosis of fistulas following trauma should not prove difficult except possibly in cases due to migrating foreign bodies.

Fistulas resulting from physical violence tend to heal spontaneously, aided perhaps by indwelling catheters, chemotherapy, and rarely colostomy. Our patient recovered with the aid of a Foley catheter and sulfadiazine. Those due to perforation by foreign bodies may also heal spontaneously following the removal of the foreign body. We have seen none of this type. Unfortunately, there is less of a tendency toward spontaneous healing in fistulas following operation. Individualization is necessary. Colostomy or cystostomy may be advisable and occasionally may suffice. If not, these procedures may be necessary as preliminaries to operation on the fistula in order to permit adequate resolution of edema and inflammatory reactions which might otherwise doom the procedure to failure. One of our cases of postoperative fistula illustrates this point and merits more detailed discussion.

CASE REPORT

The patient was a 73 year old man in whom a rectovesical fistula developed following a radical perineal prostatectomy during which the rectum had inadvertently been entered. About 8 weeks after the initial operation, an attempt was made to correct the fistula. The tract was excised and a Whitehead type of procedure performed on the rectum. The opening in the bladder was inverted and an attempt was made to interpose muscle between the bladder and rectum. The urine was diverted through a suprapubic cystostomy. The fistula recurred shortly thereafter, and the patient went home with the cystostomy and returned to the hospital 15 months later. He was prepared with the use of a Miller-Abbott tube, sulfasuxidine, and the bowel cleansing regimen commonly used before major procedures on the large intestine. At operation the fistulous tract was exposed through the old perineal scar. There

were minimal inflammatory and scar tissue reactions present. The fistula was excised, the bladder defect was inverted and repaired in two layers with chromic catgut, and the rectal defect was repaired in layers using catgut sutures for the mucosa and silk for the muscle coat. Muscle was interposed between the lines of repair. A colostomy was not done, but the Miller-Abbott tube was left in place and chemotherapy continued after operation. Convalescence was satisfactory and observation several months later found him with clear urine, voiding normally, and with no rectal leakage.

We believe this case illustrates the value, in the proper management of postoperative fistulas, of bowel and urinary antiseptics, diversion of the urinary stream, bowel defunctionalization, and the desirability of waiting until all inflammatory reaction has abated. It may also illustrate the value of nonabsorbable sutures in the muscular wall of the bowel.

The final patient in this group has steadfastly refused treatment for a rectovesical fistula which occurred after a suprapubic enucleation of a prostate which proved to be carcinomatous.

NEOPLASTIC FISTULAS

The distribution in this group was as follows. Four were secondary to carcinoma of the sigmoid, 4 to carcinoma of the rectum, primary malignancy of the bladder accounted for 4 cases and of the cervix for 2 cases. In the literature, carcinoma of the vagina and prostate are also reported as a cause of fistula.

As anticipated, exploration in the 8 cases due to cancer of the large bowel disclosed extensive inoperable lesions. Palliation by means of colostomy, cystostomy, or both was all that could be offered these patients. There are, however, cases on record in which radical excision of the carcinomatous mass involving the bladder and bowel has been successfully accomplished.

In 2 of the patients whose primary lesion was in the bladder, a similar situation prevailed. In one of these the fistula developed terminally after a ureteral transplant had been performed for recurrent cancer. In the other, thought clinically and at operation to have a sigmoid neoplasm but found at postmortem to have a primary cancer of the bladder, a palliative colostomy was done. The third patient was found at operation to have a ves-

icoileal fistula and the portion of the ileum involved was excised, an end-to-end anastomosis done, and a segmental resection performed for the bladder tumor. The patient was subsequently lost to follow-up, but at the time last seen was free of recurrence of the fistula. The fourth patient is one in whom a rectovesical fistula developed 3 years after excision of a bladder tumor followed by radium and x-ray treatment. He has, at present, extensive inguinal metastases, but he seems content to pass virtually all the urine per rectum.

Both vesicointestinal fistulas secondary to carcinoma of the cervix also had x-ray and radium treatment. Neither has had any therapy directed at the fistula. In one patient the microscopic study showed no tumor cells, the fistula evidently having resulted from radiation necrosis.

Our experience in this group of cases is in accord with that generally recorded. While in rare cases it may be possible to excise the growth and thus hope for a cure of both the tumor and the fistula, in the vast majority of cases palliation is all that can be hoped for. Colostomy is the most efficacious measure, suprapubic cystostomy may sometimes be necessary, occasionally a cutaneous ureteral transplant may add to the patient's comfort.

INFLAMMATORY FISTULAS

There were 8 cases of fistula of inflammatory origin in the present series. Two of these, both rectovesical, complicated a tuberculous enterocolitis. The 6 remaining were secondary to diverticulitis of the colon and all were sigmoidovesical.

This inflammatory group is by far the most interesting, first because of the great change in the etiology which has taken place over the years, paralleling progress in medicine, surgery and public health and improvement in medical practice, and second because these patients offer a challenge to the surgeon.

The list of inflammatory causes which have been reported includes syphilis, typhoid, actinomycosis, amebiasis, appendiceal abscess, prostatic abscess, perineal and perirectal abscess, diverticulitis of the bladder, tuberculosis of the bladder, bowel, or peritoneum, ter-

минаl ileitis and most frequently, diverticulitis of the colon and adnexal disease in women. Many of these causes are no longer reported—others are rare. The most frequent cause at present is diverticulitis of the colon, chiefly in men. The change in sex incidence and in etiology is illustrated by a comparison of the reports from the Mayo Clinic by Sutton in 1921 and Mayo and Miller in 1940.

In the former series of 34 cases, 26 were in women and 8 in men. Only 6 of the fistulas were due to diverticulitis, the majority of them resulting from salpingitis. In the latter series, 54 more sigmoidovesical fistulas were added, 45 in men, 9 in women. None followed salpingitis while 32 were due to diverticulitis.

Diverticulitis, therefore, merits special attention in relation to the problem of vesicointestinal fistula, not only because of its apparent increase in incidence, but also because the fistulas which result not infrequently lend themselves to successful surgical treatment. This is especially so since the advent of chemotherapy, antibiotics, and new techniques.

Diverticulosis of the colon has been estimated as occurring in between 5 and 8 per cent of patients with bowel symptoms of sufficient intensity to warrant x-ray examination, and diverticulitis may be expected to occur in about one-fifth of these patients. While uncomplicated diverticulosis is generally best managed by medical means, obstruction, perforation, and fistula formation convert the problem into a surgical one. The vast majority of fistulas occur between the sigmoid and the bladder, the proximity of the sigmoid to the bladder and the tendency of the inflamed diverticulum to adhere to the bladder doubtless accounts for this. The latter also accounts for the fact that the fistulas are most frequently on the left side of the bladder.

Inflammatory fistulas rarely heal spontaneously. Earlier writers treated them by diet and medicine with occasional success in cases of lues or tuberculosis. A few spontaneous recoveries are on record. Other methods used were removal of bladder stones, dilatation of rectal strictures and rectal and bladder irrigations.

Later isolated attempts at cure or palliation by surgery were made—colotomy and

cystostomy especially In 1886 Cripps wrote "The idea of abdominal section with a view to separating the intestine from the adherent bladder and closing the opening might at first be thought possible, but after reviewing numerous specimens and the accounts of post-mortem examinations, the proceeding, I fear, will be seldom practicable"

In 1899 Pascal, in his comprehensive review, referred to Dumenil and his suggestion of colostomy in 1884, and to LeDentu and his attempt to remedy the condition by a trans-vesical approach, and to Czerny who advocated laparotomy In 1915 Cunningham summed up the possible operative treatment as follows

- 1 Abdominal section, separation of intestines from the bladder, repair of openings in both organs or resection of both bladder and gut

- 2 Perineal operations, separation of bladder from gut, packing of wound and drainage of bladder by means of a retained catheter

- 3 Colotomy

- 4 Suprapubic cystostomy

In 1921 Sutton stated that 23 of his 34 patients were cured by operation and that there were 4 operative deaths He gave no details of the operations but apparently it was a one stage resection of all diseased tissue Of course most of his cases were due to salpingitis Strangely enough cures were obtained in all the tuberculous fistulas, but he does not state how many of the fistulas of tuberculous origin were not operated on In this period single stage operations of which colostomy was a part are reported

A paper on this subject was published by John Morrissey in 1931 At that time his list of surgical possibilities was the same as that of Cunningham published 15 years earlier He made the significant statement that he favored colostomy In the discussion Rankin stated that he favored Morrissey's idea of a preliminary colostomy and had tried it in 3 patients successfully After this time the stage procedure was gradually accepted and at present is generally used Preliminary colostomy is performed as the first stage, excision of the fistula and involved portions of the bladder and bowel as the second, and finally restitu-

TABLE II

	Sutton 34 cases 1906-1920	Mayo & Miller 54 cases 1921-1940
Men	8	45
Women	26	9
Diverticulitis	6	32
Acute salpingitis	9	0
Tuberculous salpingitis	3	0

tion of the bowel continuity as the final stage The reduction in mortality and recurrence rates have confirmed the multiple stage operation as the procedure of choice in the majority of cases Bowel rest, and local and general rehabilitation are facilitated, and these factors are important for a successful outcome

Of our 6 cases of fistula resulting from diverticulitis, 4 were treated by the multiple stage method Three are completely cured The other was markedly improved but a small fistula recurred Her symptoms are so minimal that she wants nothing more done One of the 2 remaining was treated by simple incision and drainage of a pelvic abscess resulting from a perforated diverticulum of the sigmoid which communicated with the bladder Pyuria and an intermittently draining sinus persist but the patient refused further treatment when last seen The final patient in this group was managed by a one stage procedure consisting of excision of the fistula, the involved portion of the bladder, and most of the diverticulum, and a suprapubic cystostomy She remains cured 1 year following operation This case is worthy of brief special mention

The universally admitted beneficial results of the sulfa drugs and the antibiotics on bowel surgery and surgical mortality rates in general, plus the newer methods of preoperative and postoperative care, particularly intestinal defunctionalization suggest the possibility that selected cases of vesicosigmoidal fistula may be managed by a one stage procedure These patients should be those in whom the fistula is associated with a minimum of inflammatory reaction and in whom the sigmoid is easily mobilized

CASE REPORT

The patient, a 62 year old woman complaining of passing gas and food particles in the urine, was found

to have a vesicosigmoidal fistula. She was prepared with bowel antiseptics and a cleansing regimen. Eleven days after admission operation was performed with the advice and assistance of Dr Lawrence Fallis. A midline lower abdominal incision was made and the peritoneum opened. A loop of small bowel was found adherent to the posterior surface of the bladder, and the sigmoid was densely adherent to the left posterolateral wall of the bladder. The bowel at this point seemed considerably thickened. However, it was fairly readily mobilized, and more detailed examination showed a diverticulum of the sigmoid attached to the bladder at the site of the fistula. The bladder was opened and the indurated thickened area was excised. The bladder was then repaired about a de Pezzer catheter. The diverticulum of the sigmoid was largely excised and the defect brought about by this closed with Lembert sutures. The anterior peritoneum was then closed in such a way as to extraperitonealize the sutured portion of the sigmoid. A drain was placed to the peritoneum at this point and an antiseptic pack was inserted down to the extraperitonealized portion of the sigmoid. Sulfu drugs, penicillin and intestinal intubation were continued postoperatively. The course was completely uneventful. Three and one-half weeks after operation the suprapubic wound was healed, she was voiding normally, and the urine was clear. A year later she remains well.

In this connection, we are privileged to cite a recent patient of Dr William Wishard and Dr Willis Gatch, of Indianapolis. A vesicosigmoidal fistula was found in a woman of 75 and after preparation of the bowel by cleansing and antiseptics, a one stage operation without preliminary colostomy was performed, a portion of sigmoid being resected and an anastomosis done. The patient has done well.

DISCUSSION

We are not advocating single stage operations for all vesicosigmoidal fistulas. In earlier days the mortality from this procedure was high. Balch, in discussing Higgins' paper, stated that at one hospital he found 4 operations of this kind had been done with 4 deaths. The safest procedure in the majority of instances is no doubt the multiple stage operation, but in selected cases the one stage operation may shorten the period of disability and prevent the trauma of repeated operations.

There is some difference of opinion as to the preferable site for the colostomy. Some advocate colostomy in the left lower quadrant so as to avoid redundant bowel above the fistula. Others favor a transverse colostomy in the

upper right quadrant to leave a clean field in the lower left quadrant for the succeeding stages. In our series we used the latter method.

SUMMARY AND CONCLUSIONS

A series of 25 cases of vesicointestinal fistula is reported. The causes of such fistulas and the methods of treatment are reviewed. The following conclusions seem justified:

- 1 Vesicointestinal fistulas are not common.
- 2 The largest number are caused by carcinoma of the bowel or bladder.
- 3 Most traumatic fistulas heal spontaneously.
- 4 Diverticulitis of the colon accounts for the great majority of the inflammatory type.
- 5 The new method of cleansing and sterilizing the bowel has rendered operation safer and surer.
- 6 In most instances a stage operation with preliminary colostomy is the method of choice.
- 7 In selected cases in which all the inflamed area of bowel can be excised or extraperitonealized, a one stage operation may be done.

THE ANATOMY OF THE HERNIAL REGIONS

I Inguinal Hernia

BARRY J ANSON, Ph D (Med Sci), Chicago, Illinois, EDWARD H MORGAN, M D,
Rochester, Minnesota, and CHESTER B McVAY, M D, Yankton, South Dakota

OVER a period of several years, the anatomy of the regions of inguinal, femoral, and obturator hernia has been studied anew in a large number of laboratory specimens. During the progress of the investigation, several specimens were encountered which served ideally for the purpose of teaching hernial relationships to classes in applied anatomy. The comparative method of presentation was followed, in so doing, fundamental morphological concepts were strengthened by emphasizing similarities and differences, and the suitability of a certain hernial technique for hernioplasty in one area was suggested for another region on the basis of fundamental likeness in structure. The plan proved to be so instructive that its employment in publications seemed to be warranted.

The three hernial regions are separated by relatively short distances, however, the elements which form their walls vary greatly in respect to strength and displaceability. These features may be outlined briefly, preparatory to more detailed discussion.

Of the three regions, the inguinal possesses the most readily displaceable barricade against herniation, consisting as it does of three superimposed layers, at least two of which are, usually, chiefly fascial in character, further weakening may occur in those cases in which a persistent peritoneal diverticulum, the processus vaginalis, offers a ready-made route through the abdominal parietes.¹ The

femoral region holds an intermediate position in respect to resistance to herniation, the canal through which a femoral hernia passes into the thigh is bounded on three sides by bone or ligaments, and on the fourth by a fascial sheath investing large blood vessels. Of the three, the obturator is the strongest, the small obturator canal, beginning as a small orifice in a heavy ligamentous plate, is surrounded by pelvic parietal musculature internally and closed externally by the superimposed muscles of the ventral aspect of the thigh.

MATERIAL AND METHODS

More than 500 body-halves have been studied for the anatomy of the inguinal region, smaller numbers for the structure of femoral and obturator areas. In the following accounts the statements will be based chiefly upon features encountered in the specimens illustrated (Figs 1 to 3), they are, however, supported by data which need not be specifically cited but which are in general agreement with the descriptions presented. For the discussion of femoral and obturator, anatomical drawings of recently dissected specimens have been prepared.

OBSERVATIONS AND DISCUSSION

1 *Superficial fascia* In each of the selected specimens hereinafter described, and in others more recently studied, the superficial fascia over the superior, or pubic, portion of the scrotum is divisible into two layers. The outer of the two is continuous with the superficial (Camper's) layer of the superficial fascia of the abdomen, the inner with the deep (Scarpa's) layer. On the abdomen the deeper of the two layers is easily distinguishable from the outer investing, or innominate, fascia of the external oblique aponeurosis.

Contribution No. 503 from the Anatomical Laboratory of Northwestern University Medical School.

¹In direct inguinal herniation the protruding mass displaces parietal vessels which in their normal disposition are not prolonged upon vascular nervous, and associated structures in this respect the direct inguinal hernia differs from the three types discussed in the present articles. The reader who may be interested in an illustrated account of the anatomy of direct inguinal hernia is referred to an earlier contribution emanating from the Anatomical Laboratory (Qt Bull Northwest Univ M School 1941 15 10 04).

2 *External oblique aponeurosis* The inguinal part of the external oblique layer is an aponeurotic continuation of the more proximal, muscular, portion (Figs 1a, 1c, and 1d) Like the fleshy portion of the stratum, it is invested on both surfaces by fascia, the external one of which is the fascia innominata (Fig 1b)

As the aponeurotic fibers approach their insertion at the linea alba, they fuse, anterior to the rectus muscle, with those of the internal oblique muscle along a curving line which is concave outward, near the pubic symphysis this line of fusion coincides with the midline of the body By this indentation a sub-aponeurotic space is provided which a large intramural hernia could occupy, in either male or female As the fibers which make up the inguinal ligament pass to an attachment upon the pubic tubercle, they depart from the neighboring aponeurotic bands which descend, as the superior crus, to an insertion at the pubic symphysis Between these diverging columns a triangular intercrural cleft exists, the apex of which may reach the muscular part of the external oblique layer at the level of the anterior superior iliac spine Only the external and internal investing fasciae bridge the intercolumnar, aponeurotic, gap (Fig 1b, at *), in this gap the two fascial layers are applied to each other back-to-back

At the medial extremity of the triangular cleft, and just cranial to the pubic tubercle, the spermatic cord passes beyond the plane of the parietal layers and receives its investment of fascia There the two fascial lamellae fuse to form the thin external spermatic fascia, in which a varying number of intercrural fibers occur (Figs 1b and 1c) A herniating mass,

after following an intraparietal course, needs only to press farther apart the already divergent crura and dilate the fascial tubes in order to gain a funicular or scrotal position

3 *Internal oblique muscle* The internal oblique layer is also trilaminar in character, being composed of a musculoaponeurotic portion covered on the outer and inner surfaces by fascia The external investing fascia is a well-defined layer which is readily separable from the contiguous inner fascia of the external oblique layer The internal investing fascia, however, is difficult to separate from the external fascia of the transversus layer at the level of the interspinous line, but readily demonstrable in the area nearer the inguinal canal Together, the lamellae form the cremasteric fascial layer, in which scattered muscle fibers are present (Figs 1a, 1c to 1e at B)

Even when the inguinal part of the internal oblique layer is predominantly muscular, fleshy fascicles become scattered near the hernial orifice Some are prolonged inferiorly as part of the wall of the hernial sac Both muscular and aponeurotic elements are usually, fragmentary in the inferomedial part of this layer (muscle fibers at arrows in Figs 1d and 1e) Just as investing fasciae bridge across the intercrural fault in the external oblique, so also the comparable fasciae of the internal oblique stratum extend across the interfascicular spaces, and remain to represent the whole layer in instances in which muscle-fibers are wanting (areas marked by asterisks in Figs 1d and 1e) The funicular part of the layer is, therefore, chiefly fascial as it constitutes the dilated and saccular covering for the hernial contents Such sparse distribution of cremasteric muscle is to be ex-

and is bounded by columnar portions of the aponeurosis (superior and inferior crura) Fig 1c The external oblique and internal oblique layers (A and B, respectively) have been drawn forward, the dissection has been carried to the level of the testis, and the layers of the spermatic cord (lettered as in Fig 1a) have been incised successively to expose the constituents of the cord and their investments The preperitoneal layer forms a definite sheath for the internal spermatic artery, the pampiniform plexus and the ductus deferens (sheath opened to show the contents) Fig 1d, The external oblique layer has been incised vertically and then turned aside to expose the broad, funnel-like, funicular portion of the internal oblique stratum (at *) The upper arrow indicates the point at which the transversus fascia sends off a lamella to invest the rectus mus-

cle The smaller arrows point to margins of the muscular portion of the internal oblique, between which edges the layer is wholly fascial (compare Fig 1e) The lower muscle fibers are prolonged upon the cord as the cremasteric muscle In the reflected portion of the external oblique the aponeurotic crura and the intercrural fascia (at A) are evident Fig 1e, The transversus stratum (at C) is shown by incising and reflecting the overlying portion of the internal oblique layer By continuing the incision toward the scrotum, the internal spermatic fascia (at *) is exposed Distally the latter envelope has been opened to show the preperitoneal (subserous) connective tissue and the peritoneal (serous) sac, D The margins of the fascial portion of the internal oblique layer, B, are indicated by arrows (compare Fig 1d)

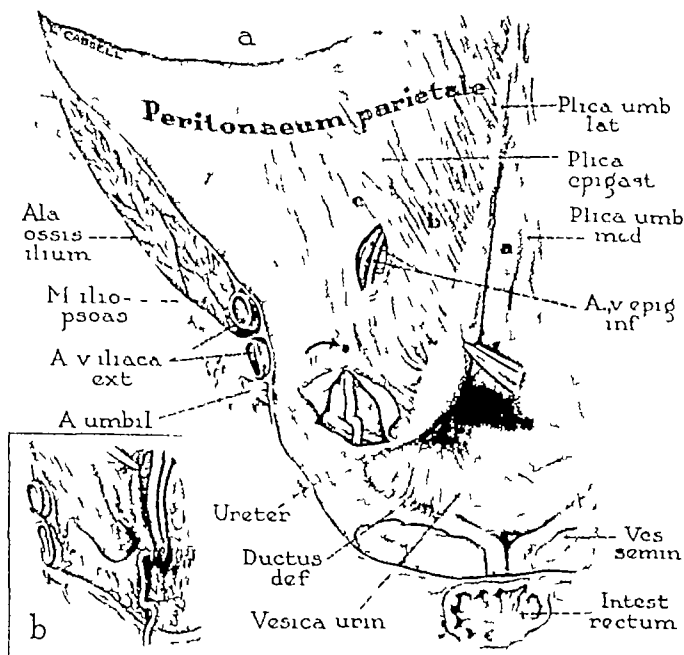

Fig 2a Dissection of the internal surface of the left half of the anterior abdominal wall of specimen II, below the umbilical level, showing peritoneal folds, foveae, abdominal orifice of the processus vaginalis and important preperitoneal structures. The specimen was sectioned coronally through the ala of the ilium just dorsal to the tuberosity of the ischium, then cut in paramedian plane to the right of the midline. The peritoneum is intact except where locally slit and turned aside to expose the inferior epigastric vessels and the ductus deferens (where the latter crosses the umbilical artery) and the external iliac vessels en route to the abdominal inguinal ring. The peritoneal fossae are lettered *a*, supravascular, *b*, medial inguinal, *c*, lateral inguinal. The arrow points to the abdominal orifice of the vaginal process of the peritoneum. The lateral umbilical fold has been elevated to demonstrate the depth of the medial inguinal fovea. Fig 2b, Further exposure of the structures near the abdominal inguinal ring. The peritoneum has been reflected to expose the epigastric vessels and the umbilical artery as the latter passes deep to the ductus deferens. The preperitoneal layer is exposed medial to the epigastric vessels and inferior to the external iliac vessels.

ected, since as the sac becomes enlarged, fleshy muscle fibers become separated by progressively greater interdistances. The cremasteric fibers, at their origins, commonly lie in the lateral and posterior segments of the mouth of the funnel-like prolongation of the internal oblique layer about the spermatic cord (lowermost arrow in Fig 1d). Even when abundant, the fibers in the funicular layer spread out in such a way as to leave only the medial aspect devoid of muscle fibers¹

¹In a recent study of 110 body halves in which no hernias occurred the cremasteric fibers in 64 per cent of cases were limited to the lateral segment of the proximal funicular portion

4 *Transverse abdominal muscle* Like the external oblique and internal oblique, the transversus stratum is trilaminar in character. Usually the muscle-fibers of the transversus layer do not extend as far inferiorly as the abdominal inguinal ring, nor do heavy aponeurotic bands occupy this distal zone. The area of herniation, then, is mainly fascial (Figs 1c to 1e). However, while principally fascial, scattered aponeurotic fibers were found in 93 per cent of 300 specimens recently examined,

of the internal oblique layer at inguinal level. At a midscrotal level however the muscle fibers were found in the anterolateral segment of the funicular layer in 61 per cent of cases.

Fig 3 The external parietal layer and the funicular continuations of the several inguinal layers (same specimen) Left inguinal region from the exterior. In the inguinal region the external oblique is exposed by reflection of the superficial fascia. In a quadrangular area over the superior portion of the intercrural fault, the external investing (innominate) fascia is reflected in order to demonstrate the corresponding internal investing fascia, the two thin fascial layers, conjoined, form the external spermatic fascia. In the scrotal area the external spermatic fascia and the other two funicular coats (cremasteric and internal spermatic fasciae) have been incised and turned aside to show the processus vaginalis and the constituents of the spermatic cord (duct and vessels). The funicular part of the vaginal process, although minute, is an uninterrupted strand from the abdominal orifice of the inguinal canal (at arrow in Fig 2a), through the length of the canal, and in the scrotum to the testis. The process widens distally to become the tunica vaginalis propria of the testis. The preperitoneal stratum, because areolar in character, is not removable as a distinct layer. In the inguinal region the superficial fascia contains a heavy deposit of fat, in the scrotum the dartos muscle replaces fat.

here, again, where heavier tissue ends, the two layers of investing fascia fuse, to become a single stratum distal to the abdominal ring. The internal, stronger, contributing layer is termed the transversalis fascia, the external, weaker, element possesses no special name, and is commonly disregarded in standard accounts. Together, on the cord, these layers form the internal spermatic fascia (Fig 1e, at *).

In the specimen illustrated, the fused muscle-fasciae form the only contribution from

the transversus layer to the covering of the cord, testis, or associated hernial mass, no muscle-fibers are present. The internal spermatic fascia, thus derived from the fascia on either side of the transversus abdominis muscle, is thin, despite its thinness, the investment is easily dissectable from the serous sac and the cremaster coat to which it is related on internal and external aspects, respectively. Although muscle fascicles are usually wanting and well-defined aponeurotic fibers always absent, the layer may contain blood vessels

The parietal part of the transverse abdominal muscle extends neither as far inferiorly nor as far medially into the inguinal region as does the overlying internal oblique muscle. Inferomedially, at the rectus sheath, the aponeurotic fibers fuse chiefly with similarly directed bands of the internal oblique proper and form a bilaminar fascial offshoot just lateral to the rectus muscle to invest that muscle (Fig 1d at uppermost arrow). In the layer which passes posteriorly to the rectus muscle, small groups of aponeurotic fibers pass to the midline, to the pubic tubercle, pecten, and symphysis.

5 *Preperitoneal connective tissue* Over the serous sac the preperitoneal, (retroperitoneal, or subserous) layer is thin, yet dissectable as a complete stratum (Figs 1c and 1d at D'). In some specimens, however, the stratum is so slight in bulk that it constitutes nothing more than a cleavage plane between internal spermatic fascia and peritoneum.

6 *Peritoneum* In a series of several hundred specimens without hernial sac or patent processus vaginalis, it was observed that not the slightest peritoneal protrusion, or even small foveate depression occurred at the abdominal inguinal ring. In many of these the inguinal layers were as completely fascial as those encountered in the current specimens. In those cases in which the vaginal process of peritoneum persists, the serous sac, once it is occupied by a hernial mass, readily dilates the surrounding fascial, or musculofascial tubes, derived from the three inguinal layers.¹

The authors agree with writers who believe that the presence of a patent serous diverticulum is the major predisposing factor in the formation of an indirect inguinal hernia.

7 *Retroperitoneal structures* Among the structures which are lodged in the fibrous stratum between the transversalis fascia and the peritoneum, the inferior epigastric artery deserves special mention, because it is mark-

edly displaced by the hernial mass. When an indirect hernia undergoes enlargement, the hernial orifice encroaches upon the medial area of the inguinal region. The obliquity of the inguinal canal is thus lost as the abdominal inguinal ring enlarges in an inferomedial direction, finally to lie deep to the site of the subcutaneous ring. As the hernial sac migrates downward and medialward, the inferior epigastric vessels are likewise forced toward the lateral border of the rectus muscle, thus reducing the area of Hesselbach's triangle. The artery comes to lie under the hernial sac, the sac itself is stopped in its excursion by the lateral edge of the muscle. Since the abdominal inguinal ring comes to lie directly behind the subcutaneous inguinal ring, the original canal—oblique in course and possessing appreciable length—is converted thereby into superimposed fenestrae whose cylindrical space is no longer than the combined—and very slight—thickness of the inguinal wall.

CONCLUSIONS

The external oblique stratum, in the inguinal region, is composed of aponeurotic fibers invested on each surface by a fascial layer. The internal oblique layer is formed mainly of muscle fibers similarly invested by fasciae. The transverse abdominal layer is formed in like manner, however, in its inferomedial portion muscle fascicles are usually wanting, being sometimes replaced by fragmentary aponeurotic fibers. In those instances in which both fascicles and fibers are absent, the investing fasciae, fused, complete the layer inferiorly.

In its course through the inguinal wall the spermatic cord carries downward an investment from each of the three layers. The lower, fascial, part of the transversus layer becomes tubular about the spermatic cord in the plane of the abdominal wall, the tube resembling a curved pipe emerging from a flat surface. The internal oblique stratum does not invest the cord tightly at its proximal end, but surrounds the cord as a broad infundibuliform investment. There is no reduplication to form an "intermediate inguinal ring", therefore, the mouth of the funnel is usually over twice the size of the abdominal inguinal ring. After

¹On the left side of Specimen II the vaginal process is of small size (Figs 2a and 2b and 3 fig 3). The abdominal orifice is approximately 1.5 mm. in diameter. There is no elevation of peritoneum over the inferior epigastric vessels; the lateral umbilical fold is 2.5 cm. high. A fetal type of urachus is present which produces an ill-defined middle umbilical fold. The vaginal process lies 6.5 cm. lateral to the midline of the specimen. The sacular segment of the process is but 0.3 cm. deep. The process is continued as a dissectable strand to the testis where it broadens to become the tunica vaginalis propria (Fig 3).

acquiring its cremasteric coat, the cord passes forward between the aponeurotic crura of the external oblique layer, carrying with it the external spermatic fascia, in tubular form, from the triangular area between the two aponeurotic crura

In advanced cases of indirect inguinal herniation, the external and internal rings are superimposed upon each other, the sac, having moved downward and medialward in fascial tissue, ultimately reaches a point where further excursion is hindered by the rectus muscle

Each of the strata which invest the spermatic cord reflects in general the character of the source layer on the inguinal wall. The contribution from the external oblique is entirely fascial, it consists of the conjoined fasciae which invest the external oblique aponeurosis. Fused into a single layer at the subcutaneous inguinal ring, it forms the external spermatic fascia.

The layer derived from the internal oblique (the cremasteric layer) is carried downward, not from the definite margins of an aponeurotic fault or cleft, but rather from a layer which regularly contains muscle fascicles in its inguinal portion. Since the fascicles displaced to cover the spermatic cord are few and attenuate, the cremasteric coat is predominantly fascial.

The portion of the transversus layer (the internal spermatic fascia) which contributes developmentally to the set of funicular coats, and, therefore, to the hernial coverings, is

that part which is situated between the arching transversus musculature superiorly and the transversalis fascia inferiorly. The layer represents a fusion of the thin outer lamina of investing fascia and the thicker inner one, the latter being the transversalis fascia.

The preperitoneal connective tissue is usually a definite layer on the inguinal wall, but it is variable in character on the hernial sac. On the inguinal parietes and within the pelvis, it houses the iliac vessels with their branches and tributaries together with the lymphatic glands and vessels. Of these retroperitoneal and retrofascial structures, the inferior epigastric vessels bear an important relation to the enlarged abdominal inguinal ring in indirect hernia, they are displaced, to lie beneath the hernial mass.

The peritoneal sac originally passes through the wall in an oblique or indirect course. Finally, when its course becomes direct, the sac gains contact medially and caudally with the displaced inferior epigastric vessels. These vessels are pressed into a position behind the rectus muscle, the muscle then constitutes the medial boundary of the hernial orifice, the triangular space of Hesselbach being obliterated. As a consequence, the inferior epigastric vessels, in being thus displaced, pass from the medial to the inferior aspect of the sac. In company with these vessels, which cross the floor of the abdominal ostium, are also situated the iliac artery and vein, the ductus deferens, the internal spermatic vessels, and certain of the external iliac lymph glands.

Pilonidal Sinus — John H Mohardt and Albert C DeFuria

PILONIDAL SINUS

Results in Ninety-two Consecutive Cases Treated by Primary Closure With Gluteus Maximus Sliding Musculofascial Graft

JOHN H MOHARDT, M D, F A C S, and ALBERT C DeFURIA, M D, Chicago, Illinois

IN 1946, Charles Pope described a new method of primary closure for pilonidal sinus (8) and together with Hudson (9) reported a series of 79 operations performed in this manner with excellent results. After all affected tissues are completely excised, the defect is repaired by means of a sliding musculofascial graft of gluteus maximus muscle and the wound is primarily closed. The salient features of the technique employed are depicted in Figures 1 through 6.

An elliptical incision is used whenever possible with the points of the ellipse in the median raphe. However, all diseased tissues must be removed. Therefore, lateral extensions are made whenever necessary. The incision is deepened to the sacral fascia and the sinus tracts are completely excised (Fig 1).

The sacral fascia is incised one-fourth to three-eighths of an inch medial to the origin of the gluteus maximus muscle and mobilization of a flap of muscle is undertaken as shown in Figure 2. The narrow border of sacral fascia attached to the muscle flap is preserved to prevent the sutures from pulling through. A line of cleavage is readily encountered upon disengaging the sacral attachment of the gluteus muscle and the musculofascial flap is developed by forcible blunt dissection laterally with the finger. The same procedure is carried out on the opposite side. Bleeding is generous but is surprisingly easily controlled with warm packs and the application of pressure for a few minutes. Only then is ligation of any remaining bleeders with plain No 00 surgical catgut carried out to obtain complete hemostasis.

Published with the permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration who assumes no responsibility for the opinions expressed and the conclusions drawn by the authors.

Three or 4 wire retention sutures are introduced through skin, fat, gluteus muscle, and sacrococcygeal fascia as shown in Figure 3. The musculofascial flaps are sutured in place, the dead space being eliminated by means of No 20 cotton suture as depicted in Figures 3, 4, and 5. No suture material is introduced into the subcutaneous layer of fat, and the skin is closed with No 0 silk or No 20 cotton. A deep mattress suture is used which everts the skin edges, particular attention being given to eversion of the skin edges at the inferior pole of the wound. If necessary, further approximation of the wound edges is gained by interrupted sutures which are placed between the mattress sutures (Fig 5).

The wire sutures are tied over a roll of gauze sponges (Fig 6) and abdominal pads are applied to cover the wound neatly. An elastic type of adhesive is then used to maintain pressure.

The present report deals with a review of 92 consecutive cases of pilonidal sinus thus treated. All of these patients were operated upon at the Veterans Administration Hospital, Hines, Illinois, during the period 1946-1948. Our experience confirms the excellent results obtained by this new closed operative method, and we believe we are justified in stating that the operation is applicable in all cases of pilonidal sinus, except in the rare type in which bone, dural, or spinal canal involvement coexist, that these patients are dismissed free of symptoms and apparently cured in a relatively short period of time, and the state of the tissues locally following this operation fortifies against recurrences.

It is not the intention of this report to evaluate the different types of surgical procedures which have been described in recent

years The operative treatment for pilonidal disease falls into 1 of 3 categories, namely, (1) the closed or primary suture method, (2) the open method with or without packing, and (3) a modified or semi-closed method

The closed or primary suture method is theoretically and practically the ideal operation However, certain fundamental difficulties of healing are encountered in this area when primary closure of the wound is attempted following excision of the diseased tissue The difficulty lies, primarily, with the dead space directly over the sacral and coccygeal fascia, and the need of obliterating this dead space with tissues which are nourished by a rich blood supply and which are adequate to fill the defect after bloc excision Motion, moisture, heat, trauma, and contamination are commonly regarded as additional factors unfavorable to healing in this region

Many techniques have been advanced in an attempt to secure adequate closure of this sacral dead space, incisions undermining the fat laterally producing flaps of skin and fat approximated by tension sutures of various ingenious designs supplemented with pressure dressings, sulfonamides, and penicillin parenterally, orally, locally, or both, and lateral incisions to permit approximation of the skin and fat without tension by the closed or semi-closed methods (6) Shute and his colleagues performed primary closure with a musculofascial flap as have Miscall and Holder As Pope (8) points out, their procedure requires greater lateral dissection to mobilize the flaps, lays fascia against fascia, and all tissue layers are apposed and sutured in the midline Others attempting satisfactory primary closure have tried skin grafting (2) or resorted to marsupialization of the incised sinus (3) It is, therefore, evident that the closed procedure is not new

In 1936, Kleckner conducted a statistical study of the recurrence rate of pilonidal sinuses operated upon by members of the American Proctologic Society Of 4,596 patients operated upon there was a recurrence rate of 23.29 per cent for the closed method and 11.13 per cent for the open method Bacon cites a large series reported by Breidenback and Wil-

son in which they obtained 94 per cent cures by the open method and 56 per cent by the closed method

The various methods all have their shortcomings Primary closures as previously performed resulted in frequent failures due to the factors previously mentioned especially the avascular base of the defect and the filling of the defect with tissues with little resistance to infection (4)

The open operation resorted to when the defect is so large that closure cannot be effected primarily is chiefly objectionable because of the long morbidity and the resulting thin scar closely adherent to the sacrum which may be easily traumatized The same objections apply when a compromise is resorted to utilizing the semi-closed procedure when primary closure would cause too great tension on the tissues

The operation involving the mobilization of the gluteus maximus muscle overcomes many of the disadvantages of all other types of pilonidal sinus operations This method permits the interposition of a gluteus musculofascial sliding graft between fat and bone, affording a resilient base for the scar in the fat

This method has a wide application as it obliterates the cavity over the sacrococcygeal region, eliminates the formation of a delicate, thin, easily abraded and broken scar, reduces scarring to a minimum, prevents deformity of the soft tissues, furnishes the tissues with a rich blood supply, supplies a mobile, elastic, resilient covering several layers thick to cushion the sacrococcygeal region over the defect, and furnishes a scar that is resistant to trauma

This series is a surgical review of 92 consecutive cases in which patients were seen during the past 2 years All of the cysts were sacrococcygeal in location, were at least inflammatory, were symptomatic, and in all instances were operated on by the closed procedure Cases of simple sacrococcygeal dimple were not included in this group Seven of the 92 cysts were quiescent at the time of operation, and all patients not demonstrating a definite sinus, associated with a history or definite troublesome symptoms or active inflammations, were not included in this report

Many of these patients required incision and drainage of an abscess, hot wet packs and sitz baths preoperatively. All cysts were termed inflammatory by reason of the pathologic report or by the presence of a purulent discharge. Many patients averaged from 3 to 7 days of preoperative care and some were operated upon in fairly active stages of localized inflammation. The immediate preoperative steps were directed to obtaining a clean operative field. This was accomplished by cleansing enemas with tap water the evening before and the morning of the operation until the returns were clear. The pubic, perineal, sacral, and anal hair was shaved over a wide area. Regular diet was allowed until midnight preceding the day of operation. Penicillin, 20,000 to 30,000 units, was started 24 hours preoperatively and continued postoperatively every 3 hours for at least 7 days. A nonresidue diet was prescribed and bowels were allowed to move spontaneously. The patients were permitted to get out of bed the day following operation or shortly thereafter if they so desired, and no particular position in bed was insisted upon postoperatively. Patients, however, were prohibited from sitting squarely on their buttocks for fear of splitting open the wound.

The results show that of the 92 cases 79 or 85 per cent, healed completely within 20 days. This group includes perfectly healed wounds and those with only minor cutaneous irritation and superficial small breaks in the skin. Thirteen patients required treatment longer than 20 days for persisting sinus, abscess, infection, and these required treatment of not longer than 5 weeks, except for 3 cases in which the wounds were opened and packed and virtually constitute repair by the open procedure. In the entire group of 92 cases the average time required for complete healing was 16 3/4 days. When severe infections occurred, the deeper structures and muscle layer remained intact and healing was relatively rapid with good covering of tissue still present over the sacrococcygeal region. Treatment consisted of incision and drainage when required, warm moist packs, frequent dressings, and irrigations with sodium chloride. Additional course of penicillin intramuscularly or sulfa

compounds or both were the chief adjuncts of therapy.

It is to be noted that all patients were discharged as healed except for 1 patient who left the hospital with his dressing and sutures on the fifth postoperative day. A follow-up study, including examination by one of us, a physician in the patient's locality, and by questionnaire, disclosed that of 51 patients contacted, all reported favorable results, that is, freedom from recurrence of drainage, except 7. Two returned with a recurrence and were re-operated upon. Five state that they have had drainage on several occasions, probably are recurrences. This constitutes a recurrence rate of less than 15 per cent to date. Thus far, about 85 per cent of all sinuses can be expected to be completely healed without recurrence and of all cases 85 per cent can be expected to be completely healed within 10 to 20 days.

The principles governing operation are no different in this region than elsewhere, infliction of a minimum of trauma, avoidance of contamination, control of bleeding by a minimum of fine ligatures and sutures, elimination of dead space, approximation of all tissue layers without tension by shunning tight suture, whether retention, skin or mattress, and careful bandaging and postoperative care of the bowels to prevent soiling, contamination, and for protection against trauma. Unless abscess occurs no subsequent dressings are necessary until the seventh to the tenth day when the sutures are removed. Continued adhesive binding of the wound is practiced to prevent undue strain and trauma for an additional few days.

CONCLUSIONS

1. Block excision with primary closure is the ideal operation for pilonidal cyst when rapidity of healing can be accomplished in the great majority of cases. Excision of all pilonidal tissue and tracts is necessary to assure against recurrence.

2. The closed operative method is not new and is practiced successfully in many cases.

3. The gluteus maximus muscle sliding graft operation is based on sound principles of surgical treatment and is applicable to all

cases except those involving bones, dura, or cord

4 The operation adequately fills all dead space with vascular muscle substance permitting resilient closure free from tension on tissues and furnishes an adequate protective pad of tissue over relatively avascular sacrococcygeal bone and fascia

5 It is our opinion that the operation itself is mainly responsible for the successful outcome in many cases, but certainly penicillin and sulfonamide therapy is a requisite

6 The results of this series justify its claims for further trial

CARCINOMA OF THE EXTRAHEPATIC BILE DUCTS

HAROLD A NEIBLING, M D, MALCOLM B DOCKERTY, M D, and
JOHN M WAUGH, M D, F A C S, Rochester, Minnesota

ON several occasions reports based on series of cases of carcinoma of the extrahepatic portion of the biliary tree have been made from the Mayo Clinic. Among these reports are those of Marshall in 1932, of Judd and Gray in 1932 and of Renshaw in 1922. Except for these and a few other such contributions from the clinic and a few from elsewhere (18, 36, 37) only isolated cases or a small number of cases have been reported by one observer.

Cases which form the basis of this report were encountered at the clinic in the forty years from 1907 through 1946. Because in many of the cases encountered in the earlier years of this period specimens available were not large enough to permit gross or microscopic examination or because perusal of the records of clinical, pathologic, and surgical findings in other cases indicated that the origin of the tumors was questionable, only 90 cases are included in this study. Unquestionably many cases of carcinoma of the extrahepatic ducts were omitted, nevertheless, microscopic or clinical proof of the site of origin of the tumor was lacking at the time this study was made.

INCIDENCE

To determine the approximate incidence of carcinoma of the extrahepatic bile ducts at operation the records of operations at the clinic for a 10 year period from 1937 through 1946 were examined. During these 10 years, about 14,000 operations were performed on the biliary tract at the clinic. The diagnosis of malignant lesion of the bile ducts was made 66 times or about once in each 210 operations on the biliary tract. Forty-one of these cases were accepted for this study. In addition, during the same period, in 4 cases malignant

disease of the extrahepatic biliary ducts was discovered at necropsy, which made a total of 45 acceptable cases during the 10 year period. The frequency of carcinoma of the extrahepatic bile ducts is compared with that of nearby structures as determined from the same series of 14,000 operations. The extrahepatic bile ducts were affected in 66 cases, the ampulla of Vater, in 44 cases, the gall bladder in 107 cases, and the pancreas in 521 cases.

As another means of determining the relative frequency of the condition, records of about 12,000 consecutive necropsies performed at the clinic were studied. This revealed an incidence of the disease of about 0.26 per cent. Other authors have found this incidence variously as 0.424 (11), 0.073 (21), 0.4 (18), and 0.45 (23) per cent.

Renshaw has given credit to Durand Fardel in 1840 for recognizing carcinoma of the common duct and for reporting the first case, and likewise, to Schueppel in 1878 for recognizing the first case of primary carcinoma of an hepatic duct.

ETIOLOGY

The etiology of the disease remains obscure since the specific cause of carcinoma remains an enigma. Inciting conditions were considered in more detail in the complete thesis. Certainly in a person who may be hereditarily susceptible to carcinoma in this region, the factor of long-continued irritation or inflammatory disease may play an important part. Robson and Dobson, White, Ewing and McGinn all thought that gall stones might play some role in the production of this disease. In our series the incidence of gall stones was 57 per cent. This incidence is much greater than that found in the clinic population as a whole, or in any comparable group. This experience, therefore, seems to corroborate previous findings supporting the supposition that cholelithiasis is a contributory factor in the pathogenesis of carcinoma of the extrahepatic bile ducts. Furthermore Boyd, Bar-

TABLE I—RELATIVE FREQUENCY OF MAJOR SYMPTOMS ACCORDING TO VARIOUS AUTHORS

Author	Cases	Sex		Per cent of cases				
		M	F	Jaundice	Pain	Palpable gall bladder	Marked anemia	Correct clinical diagnosis
McLaughlin	4	3	1	3 cases	May occur	50	Uncommon	0
Kirshbaum and Kozoll	62	44*	18*	92	42	30	Profound 19 cases	20
Stewart, Lieber and Morgan	6† 95†	73	31	100	53	26	Varying	20
Shapiro and Lufvendahl	12	9*	3*	100	83	50		0
Present series—Neibling Dockerly and Waush	90	48	42	87	61	38	Uncommon	8½

*Correction for known preponderance of men over women in hospital as differentiated from normal population revealed 55 per cent males in Kirshbaum's series and a ratio of 9 to 6 in Shapiro's series

†Cases of personal series.

‡Cases abstracted from literature

§An additional 53 per cent of cases was thought due to malignant biliary obstruction but the correct site not named

low and Dick have mentioned the close relation of the constituents of bile to carcinogenic agents and Rolleston and McNee, McLaughlin, Lee and Totten, and Rothenberg and Aronson have mentioned the ulcerative or inflammatory lesions and their relation to carcinoma of the bile ducts. That the disease can occur in the absence of the gall bladder is evident from the reports of Robertson, Robertson, and Bower from Thannhauser's case in which only a rudimentary gall bladder was found.

Papillomas in a small number of cases may be related etiologically to malignant disease. Zenker and Rolleston and co-author have supported such a theory. In our series, however, tumors of papillary type were encountered in only about 5 per cent of the cases, a papilloma as the etiologic factor, therefore, is not well substantiated in the majority of our cases. The appearance of such a tumor may be noted in Figure 1.

SEX AND AGE

The sex and age incidence in our series compare favorably with a series of good size from other institutions (18). The youngest patient of this group was a woman 23 years old. This patient seems to be the youngest whose case has been reported thus far. The majority of patients were in the 50 to 70 years of age group and there was about equal distribution in the younger and older groups. In the 30 to 39 year group were 1 man, 2 women, in the 40 to 49 year group, 6 men, 6 women, 50 to 59 year group, 11 men, 15 women, 60 to 69 year

group, 23 men, 16 women, 70 to 79 year group, 6 men, 2 women, 80 to 89 year group, 1 man, a total of 48 men and 42 women. The mean age was 61.4 years for men and for women 56.4 years.

SYMPTOMS

The relative frequency of the three major symptoms, jaundice, pain and loss of weight, in our cases shows that 87.5 per cent of men and 85.7 per cent of women were jaundiced at the onset of the disease, 56.2 per cent of the men and 66.6 per cent of the women were suffering from pain, and 79.1 per cent of the men and 78.5 per cent of the women had lost weight near the clinical onset of the disease. These factors together with a general summary of the number of cases reported and the findings of sex and age for a few of the larger series reported from other institutions may be noted in Table I.

Jaundice is the most important and most frequent symptom of the disease and occurred in about 87 per cent of our cases. The frequency with which pain was reported in this series is rather surprising in that 61 per cent of the patients had pain at some time in the course of their disease. Drapiewski in reporting on carcinoma of the pancreas likewise mentioned that pain occurs frequently. In his series about 64 per cent of patients had pain. Both carcinoma of the pancreas and carcinoma of the bile ducts are supposed to be characterized by a silent type jaundice but as these series illustrate, this is frequently not the case. The pain which may be associated with car-

carcinoma of the bile ducts characteristically is intermittent and in most cases ceases when jaundice develops. This is probably the reason for the usual concept of painless jaundice and the fact that pain often may be overlooked even by the patient.

Loss of weight is a rather constant accompaniment of the disease. The average patient lost about 26 pounds (11.8 kgm) in about 4 or 5 months prior to admission to the clinic. As a comparison, the average patient had been jaundiced for only about 2 months.

Fever or chills were rare accompaniments of the disease and when one or the other did occur it frequently seemed to accompany a secondary condition, such as a stone impacted in the duct. The small size of these tumors and the consequent small amount of degeneration within the tumor do not tend to produce fever.

CLINICAL FINDINGS

On physical examination of a patient with this disease, jaundice is probably one of the important findings. Frequently considerable pigmentation is present and a dusky hue may be noted. The depth of the jaundice is illustrated by the mean value of serum bilirubin for the entire group which was about 25 milligrams per 100 cubic centimeters with a direct reaction.

The observation (8) that when obstruction of the bile duct is due to a malignant lesion the gall bladder is found dilated and when obstruction of the duct is due to stone the gall bladder is collapsed holds good in the majority of cases. Thus the finding of a palpable gall bladder is of great diagnostic help. In only about 38 per cent of this series of cases was the gall bladder considered palpable. The gall bladder was found enlarged at operation in about 41 per cent of cases. Actually the correlation between the finding of a palpable gall bladder on examination and the proof that the gall bladder is enlarged at operation is poor. Enlargement of the liver is a more dependable finding and was noted on physical examination in 70 per cent of the cases in our series. The enlargement of the liver, inflammatory reactions about the gall bladder and gall stones probably are the most common causes of a mistaken clinical diagnosis of distended gall bladder.

Tenderness on palpation of the abdomen was noted in 38 per cent of the cases. It did not occur more frequently in cases in which either the liver or the gall bladder was enlarged. It would appear that it more frequently was associated with the various inflammatory reactions of concomitant disease of the gall bladder. Cognizance of this may help to prevent an incorrect diagnosis of simple benign biliary disease.

LABORATORY DATA

The usual laboratory examinations are not of great value in the diagnosis. Profound anemias are the exception and the concentration of hemoglobin and the erythrocyte count are only slightly decreased. Likewise, in an occasional case in which the concomitant inflammatory components to the disease are marked, leucocytes may number 12,000 or 15,000 per cubic millimeter of blood. The leucocyte counts in most cases and the mean for the series, however, were within normal limits.

The value for serum bilirubin was elevated to an average of about 25 milligrams per 100 cubic centimeters and the reaction was direct in the cases in which jaundice was associated. Indirect positive reactions were rare and generally occurred in the presence of considerable damage to the liver, as a secondary feature of obstruction.

Acholic stools were a regular accompaniment of jaundice and were noted in about 91 per cent of the cases in which jaundice was present. Biluria was in proportion to the jaundice.

Duodenal contents were aspirated in 65 per cent of cases in which jaundice was present. In 50 per cent of these cases no bile was present, in 8 per cent a trace of bile was found on one examination and none at other examinations. In 30 per cent only a trace of bile was present at any examination and in only 12 per cent was a free flow of bile found. Blood was found in the aspirated duodenal contents only 4 of the patients, and may be considered a rare finding in patients who have carcinoma of the extrahepatic bile ducts. The presence of blood in the duodenal contents was diagnostically of no help in locating the origin of the tumor within the extrahepatic bile duct.

TABLE II —PREOPERATIVE DIAGNOSIS AND THE NUMBER OF PATIENTS WITHOUT JAUNDICE IN EACH GROUP

Preoperative diagnosis	Total patients	Number without jaundice
Carcinoma of the pancreas	31	1
Malignant obstructive jaundice	14	0
Carcinoma of the bile ducts	7	1
Common duct stone or malignancy	9	1
Common duct stone	14	3
Cholecystitis with stones	5	5
Cholecystitis	1	1
Intrahepatic jaundice	2	0
Obstructive jaundice	1	0
Obstruction of the common duct and biliary fistula	1	0
None exploratory operation for indeterminate abdominal condition	2	2

PREOPERATIVE DIAGNOSIS

The preoperative diagnosis given first by the clinician was correctly stated to be malignant disease with biliary obstruction in 61 per cent of cases. However, in only about 8 per cent was the location given as definitely in the bile ducts. In 38 per cent of the cases the condition was thought to be due to carcinoma of the head of the pancreas and in 16 per cent to be due to malignant obstruction of the bile ducts, but the exact location was not named. In the remaining 39 per cent of cases the condition was thought not to be due to malignancy. The majority of patients of this group were thought to have stones of the common duct, or cholecystitis with stones or allied conditions. Of interest is the fact that all 5 of the patients thought to have cholecystitis with stones were not jaundiced. Correlation of the patients' diagnoses with the absence of jaundice may be noted in Table II.

SURGICAL TREATMENT

Numerous and varied operations have been attempted to eradicate the disease. Renshaw credited Baudoin with performing the first hepatocholeangio-enterostomy in 1896 and Cotte for suggesting a hepatocholeangiojejunostomy of the Y type. W. J. Mayo was one of the first to utilize the end-to-end anastomosis. Numerous reports (4,7,14,15,27,29)

TABLE III —AVERAGE LENGTH OF LIFE OF PATIENTS WHO HAVE DIED AFTER ONSET OF JAUNDICE AND AFTER OPERATION BY LOCATION OF LESION

Location	After jaundice		After operation	
	Patients	Average survival months	Patients	Average survival months

†Exact period of survival is unknown but known to be less than 2 months in any of the cases.

since have mentioned the use and some of the advantages of block resection of the duct with end-to-end anastomosis. The Whipple type of procedure also has been advocated by some (6,29).

In our series all types of operation from simple biopsy to the Whipple procedure were attempted. Resection of the involved portion of the duct seemed to give the best results. The subsequent anastomosis was made either by bringing the sectioned ends of the duct together as an end-to-end anastomosis or by anastomosis of the end of the duct to the duodenum or jejunum. This series seemed to confirm the impression gained in other series in which reconstructive operations were performed on the biliary tract that a Roux type of anastomosis is neither necessary nor advisable. The stomach, if mobile enough for use in the anastomosis, is also satisfactory as is probably any portion of the gastrointestinal tract. W. J. Mayo showed many years ago that even the colon can be used with a good result for the anastomosis. Palliative internal or external drainage operations were not successful in our series, this observation substantiates the findings of others (4,9,10,28,30). However, there certainly could be no objection to cholecystogastrostomy for drainage and relief of jaundice provided that the tumor will allow passage of bile through the gall bladder.

External drainage procedures in cases of malignant lesions in the bile ducts as in cases of a carcinoma of the pancreas or ampulla are not satisfactory. The problems of fluid and electrolytic balance consequent to establishment of an external biliary fistula usually outweigh the advantage of temporary relief of jaundice for a patient who is already debilitated by carcinoma.

Because of the proximity of these lesions to many vital structures, it is doubtful whether any more radical surgical approach to the problem will become satisfactory. Attempts at wider resection frequently are followed by disaster as illustrated by certain reported cases (5) in which the hepatic artery was sectioned in the region of the tumor with resultant infarction of the liver and death from hepatic insufficiency. It seems that extirpation of the involved segment of duct will be successful only in the absence of extension of the disease. Patients of this series who have lived the longest time after operation are in this group.

Course after operation. The survival rate is very poor even when optimal conditions for resection are present. The mean period of survival after operation for all patients was only 3 or 4 months, and the mean period of survival from the onset of jaundice was only a month more (Table III). One patient is still alive 2 years and 2 months after operation. Survival for this length of time occurs too seldom to change what must necessarily be a pessimistic outlook.¹

Previous observers have stated that the disease was seen early in its course (22) or that widespread metastasis is unlikely (17). It would appear from a general study of our 90 cases in which 63 per cent of the patients had metastasis at the time of operation and the average patient had been notified of illness by the onset of jaundice only about 8 weeks before operation, that the disease is not being seen early in its course. This is substantiated by the fact that in 14 per cent of cases the disease was not far enough advanced to cause jaundice and yet in three-fourths of these

Fig 1 Papillary carcinoma of low grade in the common hepatic bile duct ($\times 31$)

cases metastatic lesions or extension was noted at the time of operation.

PATHOLOGIC FINDINGS

Grossly the material was not such as to lend itself to any method of classification although generally the types of lesions present were villous (38), diffuse and nodular as Walters and Snell and others (13) have mentioned. The majority of lesions appeared as circumscribed, firm, infiltrated, grayish white nodules often obstructing the lumen of the resected duct and associated with dilatation proximally. Figures 2 and 3 illustrate this type. In a few instances a polypoid lesion was noted with actual obliteration of the duct. In the more diffuse lesions there was cordlike thickening of the involved portions. The similarity of some of these types to benign stricture has been pointed out by Bell. Extension or metastasis in many cases was the first indication to the surgeon that the condition was in fact not on an inflammatory basis. Metastatic deposits in more than a third of the cases were noted in the liver which in many instances also showed the obstructive phenomenon of hydrohepatosis (Fig 4).

Carcinoma of the hepatic ducts was found in 23 cases, carcinoma at the juncture of the cystic and common ducts in 31, carcinoma of the common duct in 29 (Fig 6) and carcinoma of the cystic duct in 3. In 4 cases the tumors were so diffuse that the exact point of origin could not be determined (Fig 5 and Table IV).

¹ Since preparation of this article this patient has returned and was found to have an inoperable recurrence at the site of the anastomosis.

Fig 2 Carcinoma of the common bile duct halfway between the cystic duct and the ampulla of Vater

Fig 3 Carcinoma of the common hepatic bile duct

Microscopically all of our tumors were of the adenocarcinoma type. Other investigators have reported a similar finding although an occasional squamous-cell epithelioma of the duct has been noted, and one author mentioned sarcoma although he did not report a case. Figures 1 and 7 illustrate some of the microscopic characteristics of the disease.

Microscopically three general types of adenocarcinoma were present in our cases: (1) a fibrous or scirrhous form, (2) a mucous form (Fig 7), and (3) in 5 cases a papillary form (Fig 1). The microscopic features are given in more detail in the complete thesis, but we wish to elaborate on certain modes of spread seen in these carcinomas and to relate these to the clinical features of pain and jaundice.

INVOLVEMENT OF NERVES

The literature on carcinoma of the bile ducts scarcely mentions the involvement of nerves

by the disease. Moore was one of the few to suggest that pain in carcinoma of the bile ducts may be due to spread of the lesion to the nerves, and Masuda reported involvement of nerves in 12 of his 15 cases. In our series involvement of nerves was studied, but serial sections or large numbers of sections were not made specifically to locate the nerves. Despite this, in 46 of the 90 cases nerve filaments were identified in sections examined. In 29 cases (63 per cent) of this group the nerves have been invaded by tumor cells. The involvement was found most frequently in the perineural sheath. Whether involvement in the sheath constituted involvement of a true space along which tumor cells might travel as in lymphatics or blood vessels, or whether the sheath merely offered a ready plane of cleavage is not clear. Less commonly the invasive tumor cells directly replaced or invaded the

Fig 4 Hydrohepatosis in a case of carcinoma high in the hepatic duct. Anatomic obstruction from the tumor was lacking

nerve bundles. This phenomenon was found in a number of cases and in some acini of tumor cells highly productive of mucus had formed a pocket of that substance within the nerve bundle. Figure 8 illustrates involvement of nerve by carcinoma. This series might be favorably compared with that of Drapiewski, who, after specifically searching for involved nerves in carcinoma of the pancreas, found invasion of nerves in 84 per cent of his cases.

Two results of neural invasion should be considered: pain and the possible physiologic cause of jaundice. Pain occurred at some time in 20 of the 29 cases in which the nerves were involved by tumor cells. As is rather characteristic of the disease, the pain ceased after the development of jaundice in 12 of the 20 cases. In 5 some distress continued after the develop-

ment of jaundice, and in 3 jaundice did not develop.

In 17 cases nerves were noted in the sections but no involvement by tumor cells was found. Only 9 of these patients had pain. This is a relatively smaller number than was found in the group in which nerves were involved.

The relationship of the involvement of nerves, metastasis and pain was studied. It

TABLE IV — GRADE OF MALIGNANCY AND LOCATION OF LESIONS 90 CASES

Location	Grade of malignancy				Total
	Grade 1	Grade 2	Grade 3	Grade 4

Fig 7 Carcinoma, grade 4, at the juncture of the common and cystic ducts with numerous signet ring cells filled with mucus ($\times 70$)

was found that in all 5 cases in which nerves were involved and pain persisted after the onset of jaundice, clinically demonstrable metastasis was present at the time of operation, whereas in 10 of the 15 cases in which nerves were involved and pain was present before but not after the onset of jaundice, metastasis or direct extension was noted at the time of operation. Although they were not recognized at the time of operation, in 2 of the remaining cases the subsequent course indicated that metastatic lesions were present. Thus in 15 of 20 cases (75 per cent) in which both involvement of nerves and pain were present metastasis also was present at time of operation.

Fig 8 Nerve involved by extension from carcinoma of hepatic duct ($\times 31$)

In 17 cases nerves were noted in sections studied but they were not involved. In 9 cases pain occurred. The pain in 7 occurred before the onset of jaundice and in the remaining 2 both before and after the onset of jaundice. In 7 of the 9 including the 2 in which pain was present both before and after onset of jaundice, extension or metastasis was noted at the time of operation. In 5 of the 8 cases in which no pain had occurred prior to operation extension or metastasis was noted at the time of operation.

MECHANISM OF JAUNDICE

Jaundice is rather uniformly found in cases of carcinoma of the extrahepatic bile ducts, and yet, the mechanism for the production of jaundice is indefinite. Many observers accept the idea of obstruction of the duct by the tumor as the main mechanism, yet in our series as in other series, many of the tumors did not anatomically obstruct the duct (Fig 4). Frequently at operation or necropsy a probe can be passed through the duct with little resistance or moderate pressure on the gall bladder may empty it. Nevertheless, the patient may appear to have had jaundice of the type produced by complete obstruction with acholic stools, dark urine, and absence of bile in the duodenal contents. In some cases pressure on the duct from without, which Ewing suggested as a cause of jaundice, may be sufficient to obstruct the duct. However,

the frequency with which actual cholangiectasis or hydrohepatosis is seen makes one wonder why the pressure of bile itself was not sufficient to force passage of the bile through the same channels that permit easy passage of a probe

Milles and Koucky suggested that the flow of bile proper might offer an essential stimulus to the rhythmic emptying of the gall bladder and the muscular contraction of the common duct. This concept may well help to explain dilatation, in some cases, of the gall bladder and ducts above the tumor

Drapiewski in commenting on carcinoma of the head of the pancreas postulated a physiologic block resulting from invasion of the wall of the duct by tumor cells and consequent inhibition of the contractibility of the lower end of the common duct. Such a cause also must be considered in the production of obstruction in cases of carcinoma of the extrahepatic ducts

Involvement of nerves and the role of the nerves in producing physiologic obstruction have been overlooked thus far. Support is given to this suggestion by the fact that in 28 of 29 cases in which nerves were involved, jaundice was present. A mechanism based on a nervous factor in the production of a physiologic rather than an anatomic type of obstructive jaundice may be postulated

Jaundice then may be the result of one or both of two mechanisms (1) an anatomic mechanism with true obstruction of the duct or (2) a physiologic mechanism, which may be related to loss or lack of contractibility from invasive processes or from loss of essential nerve impulses because of involvement of nerves, or to lack of stimulus from bile flow

SUMMARY

Carcinoma of the extrahepatic bile ducts was found in about 0.5 per cent of all cases in which operations were performed on the biliary tract at the Mayo Clinic in a 10 year period. In our series of 90 cases it occurred 14 times more frequently among males than among females. The average age of the patients was about 55 to 60 years.

Jaundice was the most common complaint of 87 per cent of patients in the series prior to

operation. Pain occurred in 61 per cent of cases at some time in the course of the disease. Loss of weight was the earliest sign of something amiss. Fever and chills were rare.

The concentration of direct reacting serum bilirubin averaged about 25 milligrams per 100 cubic centimeters. Acholic stools were noted in 91 per cent of the cases of jaundice. Aspiration of duodenal contents showed a decrease or absence of bile in the presence of jaundice.

In our series of 90 cases 26 per cent of tumors were located in the hepatic ducts, 35 per cent at the juncture of the common, cystic and hepatic ducts, 32 per cent in the common duct, and 3 per cent in the cystic duct. Four per cent of the tumors were diffuse, and no definite point of origin along the duct could be determined.

Nerves were involved in 63 per cent of cases in which nerves were found in the sections. Pain occurred more frequently in cases in which involvement of nerves was found than in other cases.

Jaundice may be due to physiologic as well as anatomic obstruction of the duct. This physiologic obstruction may be due to inhibition of nerve impulses.

Tumors of this series were all adenocarcinomas, many of which were productive of abundant amounts of mucus. Only 5 per cent of tumors assumed a papillary form.

The disease was rapidly fatal and was usually far advanced in its course when operation was performed. Metastasis or extension occurred early in the disease. Even in a small group of cases operated on prior to development of jaundice metastasis was evident in 75 per cent. The average period of survival after operation was only about 3 or 4 months and after onset of jaundice it was only about 5 months.

DETERMINATION OF THE STRENGTH OF THE CANCELLOUS BONE IN THE HEAD AND NECK OF THE FEMUR

MERVYN G HARDINGE, M D, Loma Linda, California

IN the treatment of fractures of the neck of the femur by internal fixation, success or failure depends in part on the ability of the cancellous bone of the femoral head to hold the proximal end of the fixation appliance. To determine whether the holding force of the cancellous bone throughout the

head and subcapital area of the neck of the femur was uniform or not was the purpose of the experiment

MATERIALS AND METHODS

The 94 femora used in this experiment were secured from cadavers. The moisture content of all bones was kept constant by immersion in water. The number of males and females

From the Department of Anatomy School of Medicine College of Medical Evangelists Loma Linda California.

Fig 1 The average force (in pounds) required to crush each zone in the 5 cross sections is illustrated. The areas of greatest strength are encircled by heavy lines.

Fig 2 Rearrangement in 5 frontal planes of the experimental findings showing zones of greatest strength as illustrated in Figure 1.

Fig 3 Roentgenogram of head and neck of femur showing compression and tension lamellae

Fig 4 The relationship of the lamellae to the area of greatest strength is illustrated

and the average ages are shown in Table I. The bodies from which the bones were derived were from institutional inmates whose physical activities closely simulated those of the average patients who suffer fractures of the neck of the femur. The findings are thus of practical value to the surgeon.

Consecutive cross sections of bone, $\frac{1}{4}$ inch thick, were prepared from the head and proximal

TABLE I—FEMORA USED FOR DETERMINING THE HOLDING FORCE OF THE CANCELLOUS BONE

Sex	Femora		Average age
	R	L	
Male	R	31	60.9
	L	29	
Female	R	16	70.8
	L	18	
Total	64		65.5

mal portion of the neck. A flat-nosed metal punch, $\frac{1}{4}$ inch in diameter, was used to crush the bone in specific areas of each section as illustrated in Figure 1. To avoid errors due to impact and friction the punch was driven at a uniform rate by a constant speed motor and adjusted to enter the bone to a depth of $\frac{1}{8}$ inch. The force required to crush the bone without producing compression was measured in pounds. The machine was accurate to within 0.2 per cent.

FINDINGS

The average force (in pounds) required to crush the bone was almost equal in corresponding zones in the series of right and left femora. Study of Figures 1 and 2 indicates that the maximum holding force of the cancellous bone of the head and subcapital region of the neck

of the femur lies along a tract extending from the medial end of the inferior cortex of the neck to the middle of the superior aspect of the head. It is greatest where the stress and tension lamellae are intersecting.

DISCUSSION

The findings bear a close relationship to the internal architecture of the femoral head and neck. The weight of the body is transmitted via the acetabulum to the head of the femur. The load is first borne by the superior surface of the femoral head, whence it is transferred to the inferior cortex of the neck, the latter gradually thickening from a medial to lateral direction as more and more weight is conveyed to it. Figure 3 is a roentgenogram of the proximal end of a femur. The stress or compression lamellae are seen passing from the inferior neck cortex medialward and upward, fanning out as they ascend. The arching tension lamellae may also be observed extending from the superior and medial aspect of the greater trochanter to the inferior and medial aspect of the head. In Figure 4 the zones of greatest strength in individual cross sections are arranged in their relationship to these la-

mellae. The anatomical and physiological importance of this arrangement of the lamellae is emphasized by Dixon (1910) and Koch (1917).

To take advantage of this anatomical feature in the internal fixation of femoral neck fractures, the fixation appliance should be directed in a more vertical or oblique manner than is the general practice. Thus the distal end of the fixation device would be anchored in solid cortex laterally, the shaft would rest on the thickened inferior cortex of the neck, while the proximal end would be embedded in that area of the head in which the cancellous bone possesses the maximum holding force.

SUMMARY AND CONCLUSION

The holding force of the cancellous bone of the head and subcapital area of the neck of the femur was determined in 94 femora. The area of greatest holding force was found to extend along a tract between the medial end of the inferior cortex of the neck and the middle of the superior surface of the head.

ULTRARAPID BLOOD TRANSFUSION

Clinical and Experimental Observations

VIRGINIA K. PIERCE, M.D., GUY F. ROBBINS, M.D., and
ALEXANDER BRUNSCHWIG, M.D., F.A.C.S., New York, New York

THE advantages of rapid blood transfusions are readily appreciated especially in the treatment of patients in profound shock when blood pressure readings are very low or cannot be obtained, and when peripheral pulse is barely or not at all perceptible.

A simple method for the rapid introduction of blood (intravenously) was devised by one of us (V. K. P.) and consists of a small oxygen tank to which is attached a standard reduction valve and gas flow meter. A sterilized rubber tube is attached to the valve and at the other end a needle (gauge 15). The needle is inserted through the cork in the air vent of an inverted blood filled transfusion flask (Baxter) and the standard tubing with drop filter assembly attached to the outlet in the usual fashion for administering blood by the gravity method. When the valve on the oxygen bottle is opened, oxygen passes through the air vent into the space above the blood in the flask and by exerting pressure here the outflow of blood is accelerated. The assembly can be made from equipment already at hand in the operating room and requires no special additional apparatus (Figs. 1-2). A size 15 needle is employed for insertion into the antecubital vein.

This method of rapid transfusion has been employed with satisfaction in over 100 instances and now is employed routinely on our service when indicated.

In one patient there was sudden collapse and death during the operation about 10 minutes after 500 cubic centimeters of blood had been injected in the course of 5 minutes. The operation, consisting of laparotomy in an attempt to excise a recurrent carcinoma of the corpus, had been under way about 20 minutes

when the sudden general collapse ensued. Artificial respiration, cardiac massage, intracardiac injection of adrenalin failed to revive the patient. Complete necropsy (including head) revealed no evident explanation for the sudden fatality. The heart was small and contracted. The lungs did not exhibit edema or congestion. There was no venous engorgement and no evidence of fat or air embolism. (There was no evidence to indicate that the latter could have occurred.) It was the general consensus that the fatal outcome in this case was not due to the transfusion. (Transfused blood compatible, etc.)

So far the method described has been employed only for intravenous administration of blood but it could also be used for intra-arterial transfusion. Kay and Haecker have reported a somewhat similar method for intra-aortic rapid transfusion of blood in one instance as a life saving procedure and with apparent success. The oxygen under pressure in their apparatus was used for oxygenation of the blood. Pressure for injection was obtained from the oxygen tank at first but later a sphygmometer operated by hand was employed for maintenance of pressure in the flask to accelerate the transfusion. The method we describe must be carried out under the direct supervision of a physician who devotes full attention to the procedure.

Protocols from some of the operations in which ultrarapid blood transfusions were employed are presented in the following paragraphs.

CASE 1. M. M. female, aged 40 years. Radical vaginal abdominal panhysterectomy with pelvic lymph node dissection was performed. Course was uneventful during first hour then during period of 20 minutes blood pressure dropped from preoperative level of 110/70 to 80/70. Only saline had been given intravenously. A transfusion of 500 cubic centimeters of citrated whole blood was injected in 3

Fig 1 Diagram of high pressure blood transfusion assembly B, inverted flask containing blood (Baxter), O, oxygen tank, G, airflow meter, A, sterile tubing from oxygen tank to No 15 gauge needle, K, which is inserted through air vent, F, drop filter in sterile tubing, V, leading to needle which is inserted into the vein. The oxygen led into B exerts downward pressure on surface of blood forcing the latter into intravenous tubing at increased speed

minutes. The blood pressure immediately returned to 100/70 and became stabilized at this level. Prior to transfusion anesthetist reported forehead was cold, moist, and clammy, after transfusion face became warm and dry. Convalescence from operation was uneventful.

CASE B T S, male, aged 65 years. Resection of massive leiomyosarcoma of sigmoid colon weighing 3300 grams, partial colectomy, and end-to-end anastomosis were performed. During first 20 minutes of operation considerable bleeding occurred as the tumor was being rapidly mobilized. Blood pressure dropped from 130/70 to 80/70. Two thousand cubic centimeters of citrated blood were delivered in 13 minutes during which time actual excision was carried out. There was an immediate rise in blood pressure to 120/70 at which level it was stabilized during the remainder of the operation which took 1 hour. Convalescence from operation was uneventful.

CASE C (Example of one rapid transfusion sufficient for massive resection of all pelvic viscera) C R, female, aged 36 years. Panhysterectomy with pelvic node resection, total cystectomy, pelvic colectomy, and bilateral ureteral implantation into colon and colostomy were performed—an abdominoperineal operation. During first hour and 50 minutes of operation blood loss was minimal, intravenous saline was administered by gravity. Blood pressure was 100/80. During the perineal stage the blood pressure dropped suddenly to 66/50. Five hundred cubic centimeters of whole blood were injected in 1 minute and 50 seconds. Blood pressure was 92/80 at end of transfusion. One minute later it was 104/80

Fig 2 Photograph of assembly for rapid transfusion for blood under oxygen pressure. Materials required are part of routine equipment in any operating suite or emergency room.

and remained at this level until end of the operation. Convalescence was uneventful and the patient was discharged.

CASE D (Example in which it is the impression of the authors that the patient's life was saved by ultrarapid massive transfusions) Far, female, aged 52 years. Resection of large multiple recurrent masses of leiomyosarcoma from retroperitoneal region was performed. Preoperative blood pressure was 130/80. When the abdomen was opened and the intra-abdominal tension released there was sudden hemorrhage, and 1500 cubic centimeters of blood rapidly accumulated in the aspiration bottle. The blood pressure and pulse could not be obtained. The patient was breathing very shallowly and was very pale and cyanotic. 1700 cubic centimeters of blood were injected during 7 minutes with immediate return of blood pressure to 100/80 and pulse rate determinable at 120 per minute. At the close of the operation 1 hour and 10 minutes later, the blood pressure was 110/60, pulse 100. During convalescence there was no evidence of hepatic damage from "citrate intoxication." Five months later she was seen again as an out patient, had been doing a moderate amount of housework and felt well. However,

there was recurrence of the neoplasm in the lower abdomen and no further treatment was considered

In many other instances 500 cubic centimeters of citrated blood were injected in $1\frac{1}{2}$ to 3 minutes

The question arises as to whether or not high speed transfusion may entail certain risks by too rapidly increasing the circulatory volume and thereby cause cardiac dilatation with failure. Information in this direction was sought by the following experiments carried out in dogs

I Dogs will tolerate rapid intravenous infusion of isotonic (5 per cent) glucose solution in large quantities

Experiment 1 Dog 19, weight 21.9 kilograms. Nembutal anesthesia was used. Oxygen pressure assembly for ultrarapid intravenous (femoral vein) infusion. One thousand cubic centimeters of 5 per cent glucose were injected in $4\frac{1}{4}$ minutes, no pause. One thousand cubic centimeters of 5 per cent glucose were injected in $2\frac{3}{4}$ minutes, $2\frac{1}{2}$ minute interval. One thousand cubic centimeters of 5 per cent glucose were injected in 2 minutes.

During a period of $11\frac{1}{2}$ minutes 3000 cubic centimeters of 5 per cent glucose were injected. Thirteen minutes after the last injection there were râles throughout both lungs, respirations appeared labored, pulse varied from 140 to 150 per minute, the abdomen appeared distended, and felt cold. The systolic blood pressure remained at practically constant levels, 110, 120 millimeters of mercury.

After several hours the animal recovered and the next day appeared normal.

Experiment 2 Dog 28, weight 17.2 kilograms. Procedure carried out as above. Five hundred cubic centimeters of 5 per cent glucose were injected in $1\frac{1}{2}$ minutes, 1 minute interval. One thousand cubic centimeters of 5 per cent glucose were injected in $3\frac{1}{2}$ minutes, 4 minute interval. One thousand cubic centimeters of 5 per cent glucose were injected in $3\frac{1}{2}$ minutes.

Over a period of $8\frac{1}{2}$ minutes 2500 cubic centimeters of 5 per cent glucose were injected.

In this animal pulmonary edema did not develop and recovery was satisfactory. Blood pressure remained constant. The animal died 1 week later presumably of infection of the operative wound in the left inguinal region.

Experiment 3 Dog 27, weight 16.4 kilograms. Procedure carried out as above. One thousand cubic centimeters of 5 per cent glucose were injected in $2\frac{1}{2}$ minutes. Increase in blood pressure (systolic) from 135 millimeters to 145 millimeters of mercury, 3 minute pause. One thousand cubic centimeters of 5 per cent glucose were injected in $4\frac{1}{2}$ minutes, 6 minute pause. Five hundred cubic centimeters of 5 per cent glucose were injected in $3\frac{1}{2}$ minutes.

Over a period of $19\frac{1}{2}$ minutes 2500 cubic centimeters of 5 per cent glucose were injected. Following injection respirations were labored, blood pressure remained at 135 millimeters of mercury (systolic). Recovery was complete in a few hours.

II In dogs not previously bled, rapid intravenous injection of large quantities of heparinized citrated blood apparently overloads the circulatory system and causes fall in blood pressure. The blood employed in these experiments was obtained by exsanguination of other dogs.

Experiment 4 Dog 21, weight 22.7 kilograms. Nembutal anesthesia was used. Oxygen pressure assembly for ultra rapid intravenous (femoral vein) infusion of dogs blood. Three hundred cubic centimeters of blood were injected in 3 minutes. Pulse increased from 136 to 180 per minute. Respiration rose from 14 to 20 per minute. There was no change in blood pressure (120 systolic). Two minute interval. Two hundred and fifty cubic centimeters of blood were injected in 6 minutes. Pulse rose to 200, respiration 12, blood pressure fell to 110 (systolic). One minute interval. Three hundred cubic centimeters of blood were injected in $3\frac{1}{2}$ minutes. Pulse 200 (arrhythmic), respiration 8-12, blood pressure 110 (systolic). Two minute interval. Six hundred cubic centimeters of blood were injected in $4\frac{1}{2}$ minutes, pulse 180, respiration 11, blood pressure fell to 90 (systolic). Received 1500 cubic centimeters of blood during 20 minute period. At close of experiment 20 cubic centimeters of 10 per cent solution of calcium gluconate were injected. Following recovery from anesthesia animal appeared normal.

Experiment 5 Dog 16, weight 12.8 kilograms. Rapid infusion of blood as above. Six hundred and twenty cubic centimeters of blood were injected in 10 minutes. Pulse rose from 92 to a rate too rapid to count, respiration dropped from 18 to 12, blood pressure (systolic) rose from 111 millimeters of mercury to 120 millimeters. No rest period. Four hundred cubic centimeters of blood were injected in 7 minutes. Pulse too rapid to count, respiration and blood pressure unchanged. Two minute interval. Two hundred cubic centimeters of blood were injected in 3 minutes. Pulse too rapid to count, respiration 16, blood pressure 115 millimeters (systolic). One thousand two hundred and twenty cubic centimeters of blood were injected during period of 22 minutes. Recovery uneventful.

Experiment 6 Dog 22, weight 18.7 kilograms. Rapid infusion of blood as above. Five hundred cubic centimeters of blood were injected in 4 minutes. Blood pressure fell from 128 millimeters of mercury to 90 millimeters (systolic). Pulse from 120 to a rate too rapid to count, respiration 16 to 18. No rest period. Five hundred and fifty cubic centimeters of blood were injected in $4\frac{1}{2}$ minutes. Blood

pressure rose from 55 to 85 (systolic), respiration 16 to 20, animal appeared cyanotic. Clonic convulsions. No calcium gluconate injected. Received 1550 cubic centimeters of blood during period of 13½ minutes. Recovery complete and uneventful.

Experiment 7 Dog 17, weight 12.4 kilograms. Rapid infusion of blood as above. Seven hundred and fifty cubic centimeters of blood were injected in 10 minutes. Blood pressure fell from 140 (systolic) to 50 and then returned to 110, 1 minute rest period. Seven hundred and fifty cubic centimeters of blood were injected in 9 minutes. Blood pressure fell from 120 to 43 (systolic). Three minutes after injection animal died (respiration ceased). Necropsy revealed heart dilated but lungs were not congested. The liver appeared large.

Experiment 8 Dog 27 A, weight 22.3 kilograms. Rapid infusion of blood as above. Two hundred cubic centimeters of blood were injected in 2 minutes, no rest period. Four hundred and fifty cubic centimeters of blood were injected in 3 minutes. Blood pressure 130 millimeters (systolic), respiration 14, pulse 120. One minute rest period. Blood pressure 120 millimeters (systolic), respiration 20, pulse 180. Three hundred and fifty cubic centimeters of blood were injected in 3 minutes. Blood pressure fell rapidly from 120 to 35 millimeters (systolic), respiration to 10 and at end of injection animal was dead. One thousand cubic centimeters of blood were injected in 9 minutes. Necropsy showed the heart to be dilated and filled with blood, the liver was congested and enlarged, no pulmonary edema.

EXPERIMENTAL RESULTS

The studies on dogs indicate that relatively very large quantities of water (as an isotonic glucose solution) may be injected intravenously and the acute pulmonary edema that ensues in some instances, is recovered from, without apparent permanent disturbances. It would seem that the entire organism rapidly absorbs the water which passes out of the circulation into the tissues.

In regard to relatively large quantities of blood injected, 4 of the 5 animals exhibited evidence of overloading of the circulation with obvious impairment in cardiac action as evidenced by fall in blood pressure and increase in pulse rate with irregularity. In contrast to the situation where water is injected blood plasma proteins (and the red cell mass) do not rapidly pass out of the circulation but remain within it affording a rapid and more stable increase in the circulating volume than obtains when isotonic glucose is injected. Two of the 4 animals that exhibited deleterious effects died at the close of the injection experi-

ments. The appearance of the blood pressure curves resembled those that might have been obtained had the animals been subjected to severe hemorrhage with the development of shock. This is paradoxical, however, because of the fact that in these experiments excess blood was added rapidly to the circulation rather than being taken from it by rapid loss from hemorrhage.

It would appear that rapid injection of blood in large quantities to human patients might be harmful if there were no shock due to blood loss but inasmuch as blood loss is the indication for rapid transfusion the danger does not appear until blood loss has been compensated for and blood pressure has returned to normal.

DISCUSSION

Without entering into detailed discussion, it would seem, in the authors' opinion, that the advantage of intra-arterial transfusion is the rapidity of increase in the circulating volume which this method affords (2). Ultrarapid transfusion via the venous system, possible by the method here described, affords the same advantage.

There are two factors which constitute serious dangers in the employment of ultrarapid blood transfusion by oxygen under pressure in man. First, the possibility of rapid overload of the heart by excess quantities of blood injected into the circulation producing cardiac dilatation and failure. With patients in shock due to blood loss this danger does not exist at first but once approximate replacement has obtained and blood pressures are near the patient's normal, care must be exercised in continuing transfusions. Second, the possibility of embolism. A physician must devote full attention to the procedure and avoid emptying the infusion system by the oxygen under pressure with oxygen then being injected into the vein.

Ultrarapid transfusion is indicated during operations when there is sudden circulatory collapse from severe hemorrhage. The prompt restitution of blood pressure to adequate levels obviates the severe noxious effects of general tissue anoxia which are directly proportional to the length of time that the patient is in

shock. It would also thus prevent a duration of shock until the irreversible stage is reached. Ultrarapid transfusion also is indicated in those cases in which there has been appreciable blood loss and before evidence of shock has been manifested. This is a prophylactic measure for shock.

Another advantage of ultrarapid transfusion would appear to be the facility it affords for coping with numbers of patients needing emergency transfusion for shock such as would obtain in civilian disasters or in military action. Several transfusion sets as described

would permit the transfusion of one to two or more units of blood or plasma per patient in a relatively much shorter time than if a similar number of patients received the same treatment by the gravity method and obviously many more patients could be transfused in a given interval than could be possible with the gravity method.

CONTINUOUS LUMBAR PARAVERTEBRAL SYMPATHETIC BLOCK MAINTAINED BY FRACTIONAL INSTILLATION OF PROCAINE

JAMES R THOMASON, M D , and WILLIAM H MORETZ, M D , F A C S , Salt Lake City, Utah

IN many diseases and injuries of the extremities, it is desirable to interrupt the sympathetic impulses for a few hours or even for several days

Numerous methods of abolishing vasoconstrictor tone have been used. Alcohol intoxication has long been known to cause a striking degree of vasodilatation in the skin. Scott and Morton (10) described this phenomenon as occurring under general anesthesia. The value of spinal anesthesia for paralyzing the sympathetic nerves to the lower extremities has been reported by Brill and Lawrence, Morton and Scott (9), and others. Sir Thomas Lewis was the first to advocate blocking of the peripheral nerves for relief of vasospasm. In 1926, Brown used artificial fever produced by injecting foreign proteins intravenously to produce vasodilatation. Alcohol may be injected around the sympathetic ganglia to block the impulses for longer periods. The work of Leriche, White (17), and many others has made paravertebral injection of a local anesthetic the most commonly used method of obtaining temporary paralysis of the sympathetic nerve supply to the extremities. The intermittent injection of a local anesthetic agent is used frequently, both as a therapeutic measure and as a diagnostic test to determine preoperatively the results which can be expected from a surgical sympathectomy.

Most of the methods are impractical from a clinical standpoint. The administration of a general anesthetic is obviously not a desirable method of producing paralysis of the sympathetic nerve supply to an extremity. The use of foreign proteins to produce a febrile re-

sponse and accomplish the same purpose is also impractical. Spinal anesthesia is not without risk and the patient's extremities are temporarily paralyzed. In some vasospastic conditions this paralysis is undesirable since it would be preferable to have certain patients ambulatory while the sympathetic impulses to the extremities are interrupted. Complications such as neuritis and the dangers accompanying improper injection limit the usefulness of alcohol injections. Although rare instances have occurred in which procaine hydrochloride has been injected into the subarachnoid space which occasionally extends out over a spinal nerve, or into a blood vessel, paravertebral procaine block is one of the safest and the most widely used of the methods mentioned.

Procaine injected around the sympathetic chain interrupts the impulses for only a short period. Particularly when a procaine block is being used therapeutically, the injection frequently must be repeated at intervals. Often there is considerable discomfort associated with this procedure. Many patients object to it and a few will refuse. Of less importance is the fact that repeated blocks are time consuming for the surgeon.

In an attempt to overcome the disadvantage of having to do repeated lumbar sympathetic blocks, when indicated, and to increase the therapeutic uses of this method of interrupting the sympathetic impulses, we have performed a continuous paravertebral sympathetic block maintained by intermittent injection of procaine hydrochloride through an indwelling tube left in place for several days. This method has been used on 15 patients with no complications.

EQUIPMENT

The equipment, which is the same as that used for a continuous spinal anesthetic, in-

From the Department of Surgery, University of Utah Medical College.

Work made possible through a grant from University of Utah College of Medicine Research Committee Fund.

Fig 1 Lateral and anteroposterior views of the Tuohy catheter in place beneath the transverse process of the second lumbar vertebra. Arrow points to tip of catheter

cludes a No. 16 Tuohy needle with a Huber directional point, and a No. $3\frac{1}{2}$ Tuohy catheter,¹ a No. 23 needle with a blunt end, a plug to fit into the hub of the needle, and a sterile test tube. We have found that a half length of a Tuohy catheter is long enough to serve our purposes. The cost of the equipment is small.

TECHNIQUE

With the patient lying on the side opposite the one to be injected, the Tuohy needle is inserted according to the technique of Labat just beneath the transverse process of the second lumbar vertebra. The Huber directional needle point is toward the midline. The catheter is then inserted through the lumen of the needle until it reaches the distal end of the needle. While the catheter is held in place with one hand the needle is removed by sliding it off the catheter with the free hand (Fig. 1). A blunt pointed No. 23 needle is inserted into

the free end of the catheter. Procaine is injected through the catheter at the site of the lumbar sympathetic chain. We have used 8 cubic centimeters of 1 per cent procaine mixed with 30,000 units of penicillin for each injection. Between injections the needle is closed with the metal plug, and, with the catheter still attached, it is placed in a sterile test tube, which in turn is closed with a sterile cotton stopper. An abdominal pad is placed over the catheter. This pad and the test tube are fixed to the side of the patient with adhesive. These steps are illustrated in Figure 2.

Since there is a possibility of local infection around the catheter when it is left in place for a number of days, penicillin has been injected with the procaine. No evidence of such infection has occurred to date.

By diffusion the procaine comes in contact with the second and third lumbar ganglia and frequently reaches the first lumbar ganglion. To demonstrate this, a block was performed on a young male, by the method described, and 8 cubic centimeters of 35 per cent diodrast was injected through the Tuohy catheter. Roentgenograms were taken 5 minutes after the injection to show the diffusion of the contrast media (Fig. 3).

In the 15 patients on whom this procedure has been used there was either subjective or objective evidence, or both, of a satisfactory block with the exception of 1 case. Thermocouple measurements of skin temperatures were made before and after the block in each case, and in some instances oscillometric readings were recorded at the same time. Voluntary suggestions of subjective responses by the patients were noted.

White (18) and others have reported that a procaine block produces temporarily all the effects of sympathetic ganglionectomy, i.e., complete blocking of the vasomotor nerves, for a period of from 2 to 4 hours. Objective and subjective findings in a number of our cases of single injections confirmed this statement. In each of these it was found that the maximum elevation in skin temperatures lasted $2\frac{1}{2}$ to 3 hours after the block. At the end of 3 to $3\frac{1}{2}$ hours, the temperature readings were slightly elevated, but were decreasing toward the preblock level. Although this

¹The Tuohy catheter is similar to a ureteral catheter except that the distal opening is at the end instead of on the side near the end.

Fig 2 Diagrammatic sketch of continuous paravertebral lumbar sympathetic block. A, Patient on side with Tuohy catheter in place. B, Distal end of catheter in sterile test tube with needle inserted in catheter and metal plug in hub of needle. C, Tuohy needle introduced beneath transverse process of second lumbar vertebra. Catheter being inserted into the needle. D, Needle being withdrawn and catheter left in place.

duration varies with the individual patient, we believe that injections every 3 hours give a fairly continuous interruption of the sympathetic impulses.

Seven of the patients listed in Table I had previously had single injection type of sympathetic blocks involving 2 to 4 lumbar ganglia. Two of them refused any further blocks of that sort but agreed to have a continuous procaine block tried. Both of the patients were extremely pleased with the procedure. The other 5 voluntarily stated that they much preferred the continuous block which did not have to be repeated.

Table I lists the patients on whom this procedure has been used and the results obtained.

DISCUSSION

Acute thrombophlebitis Ochsner and DeBakey treated 15 patients with acute thrombophlebitis with procaine blocks. They observed that pain was promptly relieved in

many cases after the first injection and in all cases after the second or third injection. The fever disappeared in 1 to 8 days and the swelling in 3 to 12 days. For lower extremities four needles were inserted from the first to the fourth lumbar ganglia and 5 cubic centimeters of procaine injected through each. They stated that the injections should be repeated every 48 hours as long as the fever persists. Others use the return of pain as their criterion for determining when to repeat the block. Interruption of the sympathetic impulses for the required length of time is more easily accomplished by maintaining a continuous type procaine block. The pain which recurs in some patients between single injections is continuously relieved.

CASE 4 A 48 year old male had had acute thrombophlebitis of the right leg with severe pain for 2 days. A continuous block gave complete relief of pain. The edema began to subside gradually. On discontinuing the block after 4 days, his pain re-

TABLE I—SUMMARY OF PATIENTS ON WHOM THIS TYPE OF CONTINUOUS SYMPATHETIC BLOCK HAS BEEN USED

Case No Patient	Age years	Diagnosis	Duration of disease before block	Duration of block days	Results of block	Complications
*1 FM	63	Arterial insufficiency with arterio-sclerotic gangrene left little toe Large gastric ulcer	3 weeks (gangrene)	10	Good temperature response Pain relieved. Gangrene progressive Amputation required	None
2 LL	60	Varicose veins Chronic leg ulcer	6 weeks (ulcer)	3	Satisfactory response	None
3 LH	19	Chronic ulcer rt.	18 months	6	Good temperature response. Leg felt warmer to pt Ulcer much cleaner	None
*4 EF	48	Acute thrombophlebitis rt leg	4 days	8	Good response Complete permanent relief of pain	None
5 RS	61	Chronic venous insufficiency	20 years	2	Satisfactory block	None
6 CW	39	Bilateral venous stasis and chronic leg ulcers secondary to bilateral femoral and saphenous ligations Deep thrombophlebitis	1 year	6	Good response Pain relieved Edema diminished Sympathectomy	None
*7 GF	73	Occlusive arterial disease associated with thrombosis rt femoral artery	3 weeks (thrombi)	6	Good response Pain relieved Ulcers much cleaner (No sympathectomy required)	None
*8 WE	78	Occlusive arterial disease left femoral embolus	1½ days (thrombus)	6	Good response Pain disappeared 2nd day after block (no sympathectomy required)	None
*9 IH	59	Varicose ulcer with marked cellulitis lymphangitis	2 weeks (cellulitis)	4	Good temperature response Complete relief of pain Infection subsided	None
10 WL	84	Frostbite of feet Pneumonia Diabetes	3 hours (frostbite)	2	Slight temperature rise No significant change	None
11 WO	32	Buerger's disease Large ulcer rt. foot	9 years	4	Good response Complete relief of pain Sympathectomy	None
12 DS	65	Arteriosclerotic gangrene Cellulitis 5th left toe	3 weeks (gangrene)	3	Good temperature response Gangrene and cellulitis progressed Amputation required	None
*13 WD	31	Elephantiasis and cellulitis right leg	5 years (elephantiasis 2 days cellulitis)	5	Good response. Pain relieved Cellulitis subsided	None
14 EM	74	Arteriosclerotic gangrene left 2nd toe. Diabetes	3 months (gangrene)	4	Good temperature response Pain relieved Sympathectomy (amputation of toe required)	None
*15 CW	63	Ruptured arterial aneurysm (right femoral)	3 days	5	Slight temperature elevation rt thigh Pain diminished Sympathectomy performed with no additional benefit	None

*See discussion in text for further elaboration of these cases

turned within 6 hours. The block was again started and continued for 4 more days, this time with permanent relief of pain. Pain is permanently relieved in some instances by a single injection block, but usually the relief lasts only 24 to 48 hours. The return of pain in less than 6 hours after a continuous block for 4 days in this patient suggests that he would have required many individual injections.

Cellulitis associated with pain. Although we are unaware of any previous use of sympathetic blocks in the treatment of painful cellulitis, Cases 9 and 13 are representative of this condition in the lower extremities. In each complete permanent relief of pain followed institution of a continuous procaine block of 4 or 5 days' duration respectively. When the

blocks were discontinued, the erythema and swelling had subsided. Although both patients received chemotherapy, they appeared to respond more rapidly than previous patients treated with chemotherapy alone. It is possible that the relief of vasospasm, in addition to relieving the pain, may have aided in overcoming the inflammatory process.

Acute arterial deficiency. Acute arterial deficiency may result from a gunshot wound, a traumatic laceration, an embolus, surgical ligation of a normal artery, ligation or excision of a peripheral aneurysm, or spontaneous rupture or thrombosis of an aneurysm. In all these conditions, the main vessel flow is effec-

tively blocked and may be still further occluded by both distal and proximal thrombosis

The effect of associated vasospasm on the collateral circulation is extremely important. The only possible blood supply to points distal to the obstruction or site of injury is through the collateral circulation. For varying reasons an added surgical sympathectomy is often inadvisable in these cases, even though its effect is urgently needed.

Gage and Ochsner reported a number of successful results following sudden occlusion of major peripheral vessels by repeated sympathetic blocks. Smithwick preferred alcohol injection in treating patients in shock or the average case of embolic occlusion. The injection of alcohol in this region is not without danger and complications. A continuous procaine block gives results comparable to those of a surgical sympathectomy, during the acute period, and avoids the disadvantages of alcohol injection.

CASE 7 A 73 year old female had severe cardiac disease and right femoral thrombosis of 3 weeks' duration. Her leg was cool, somewhat cyanotic, and there were some ulcerations of the calf associated with marked pain. A continuous block of 6 days' duration relieved the pain and the ulcers became smaller and much cleaner. The ulcers subsequently responded to further conservative local treatment. Improvement in collateral circulation during this period was apparently sufficient to care for the nutrition of the leg.

CASE 8 A 78 year old male had a left femoral embolus of 36 hours' duration. The left leg was cool, cyanotic, and extremely painful. On the second day following institution of a continuous procaine block, his pain disappeared, the color and temperature of the leg improved. The block was discontinued after 6 days. He was discharged 4 days later ambulatory and without any pain.

CASE 15 A 63 year old male had an arterial aneurysm in the right thigh which ruptured. The aneurysm and accompanying femoral vein were excised and the femoral artery and vein ligated proximally and distally. The right leg became cold from the mid thigh down. A continuous sympathetic block was maintained for 5 days and there was a slight constant skin temperature elevation in the right thigh. The block was discontinued and a right lumbar sympathectomy done. Postoperative skin temperature determinations were the same as those obtained during the continuous block. The sympathectomy was no more effective than the continuous block. Ultimately the leg was amputated above the knee.

Fig 3 Lateral and anteroposterior views showing distribution of 8 cubic centimeters of 35 per cent diodrast in retroperitoneal space along lumbar sympathetic chain, following injection through Tuohy catheter

Arteriosclerosis associated with vasospasm
Goodman, Messinger, and White stated that in arteriosclerosis associated with vasospasm if the extremity is cold and moist and there is a fair response to a temporary block of the sympathetic outflow, a single preoperative diagnostic procaine block often does not give an accurate prediction of the result which will follow a surgical sympathectomy. Most of these patients are elderly and often are poor operative risks. A continuous temporary chemical block for a number of days would seem to offer a better preoperative diagnostic test of the result to be expected from a surgical sympathectomy. In some instances, this obviates a needless surgical procedure.

CASE 1 A 63 year old male had bilateral arterial insufficiency of the lower extremities, gangrene of the left little toe, and a large gastric ulcer which was suspected of being malignant. Although the patient was a poor candidate for any surgical operation, there was the problem of possible amputation of the left leg and subtotal gastric resection. Whether or not a sympathectomy would increase the circulation sufficiently to prevent spread of the gangrene and permit amputation only of the left little toe was un-

certain A continuous sympathetic ganglionic block of 10 days' duration was done while the patient was being prepared for subsequent surgery Although a satisfactory block with complete relief of pain was obtained, the gangrene slowly spread to involve the foot The progression of the arteriosclerotic gangrene, in spite of a chemically produced sympathetic ganglionectomy of 10 days' duration indicated that a surgical sympathectomy would have been futile A left mid-thigh amputation was performed His general condition improved rapidly and 2 weeks later a benign peptic ulcer was successfully removed by subtotal gastric resection

Causalgia, painful neuroma, phantom limb, and stump pain of the lower extremity Reports concerning the treatment of causalgia with repeated procaine blocks have been variable Ulmer and Mayfield in a series of 75 cases reported immediate temporary relief of pain lasting from 1 to 3 hours in every instance following a procaine block In some of their cases blocks were repeated 4 to 8 times Some of their patients were improved for long periods of time but none of them obtained complete permanent relief of pain Homans on the other hand reported permanent relief in some patients treated with repeated blocks Rasmussen and Freedman found that of 100 patients, 13 had complete permanent relief following 1 to 3 procaine blocks and 32 had sufficient relief of pain so that further treatment was not required Shumacker, Speigel, and Upjohn reported satisfactory alleviation of symptoms in 21 of 83 patients receiving 1 to 5 injections of procaine

White (16) and others have reported successful results in the treatment of painful neuromas, phantom limb and stump pain of the lower extremity with single or repeated procaine blocks As in causalgia, opinions of the authors have varied as to the success of repeated blocks if the first one did not give permanent relief

It is possible that in these conditions a continuous type sympathetic block for a number of days would relieve all of those who have in the past responded to single or repeated injections and, in addition, some who previously required surgical sympathectomy

CONCLUSIONS

The series of patients on whom a continuous type temporary chemical interruption of the

sympathetic impulses to the lower extremities has been used is small However, we have been impressed by the results obtained

A more continuous interruption of the sympathetic impulses is provided Decision as to the need for surgical sympathectomy is more conclusive by its more prolonged effect The effect of interrupting the block may be observed by injecting penicillin solution without procaine The block may be restarted by simply adding procaine again to the injections This is occasionally a desirable feature

The discomfort to the patient of repeated blocks is avoided It is as easily performed as the usual paravertebral block Subsequent injections can be made by the attending nurse

The chief disadvantage of this method is the possibility of infection around the catheter This has not occurred and we believe that injection of penicillin with procaine will help to prevent it

SUMMARY

A method of maintaining a continuous type lumbar paravertebral sympathetic block is described This is performed by placing a No 3½ indwelling catheter in the vicinity of the second lumbar ganglion and injecting procaine mixed with penicillin every 3 hours The equipment necessary and the technique of the procedure are given

Its effectiveness has been demonstrated in patients with acute thrombophlebitis and in those with painful cellulitis In these conditions the vasospasm and the pain are relieved continuously while the block is maintained This effect is achieved without the necessity of repeatedly placing needles in the region of the sympathetic chain It is suggested that not only is the continuous type block more convenient and less bothersome for the patient and the surgeon but also probably more effective in promoting the return to normal of the areas of inflammation

The method has been used in several patients with acute arterial insufficiency, such as embolism to the femoral artery In this type of condition, it is believed that a more satisfactory evaluation of the adequacy of collateral circulation after release of vasospasm can be made by a continuous type block than by a

single or repeated single blocks. There is also a good possibility that a prolonged block of 7 to 10 days' duration may satisfactorily tide the patient over the most critical stage of circulatory embarrassment. A sympathectomy may be made unnecessary in some of these cases. In others the sympathectomy may be delayed for a number of days until the patient is in better condition for the operation.

In patients with chronic arterial insufficiency, such as arteriosclerosis, this type of block may be of considerable value. Evidence of the presence or absence of vasospasm is provided. There is the added advantage with the prolonged block that the effect of the release of vasospasm upon the nutrition of the extremity can be evaluated much better. There may be *no real evidence of improved nutrition* to a cyanotic toe with a single block, whereas a prolonged block of 10 days' duration is more likely to give evidence of improved circulation. In such conditions, therefore, a better test is provided for determining what may be expected from a sympathectomy.

By being provided a more prolonged release of vasospasm and relief of pain in cases of causalgia and related conditions, some patients may be relieved who formerly required sympathectomy.

Theoretically and on the basis of these observations, it is felt that there may be a wide clinical application for continuous paravertebral sympathetic blocks.

REPAIR OF THE COMMON BILE DUCT OVER A BURIED CATHETER

WILLIS G. DIFFENBAUGH, M.D., F.A.C.S., and SELIM W. McARTHUR, M.D.,
Chicago, Illinois

INJURIES to the bile ducts during the course of operations upon the gall bladder or ducts and the strictures resulting therefrom are among the most distressing complications of the surgery of this region. Anastomotic procedures are prone to result in stricture and frequently too great a gap is present between the proximal and distal portions of the duct for anastomosis to be done. Anastomotic procedures between the cut proximal end of the duct and bowel are frequently followed by ascending cholangitis, recurring jaundice, and suppuration because of the loss of the sphincter of Oddi and stricture formation at the anastomosis. The use of the Roux-Y principle of a defunctionalized loop of small bowel as advocated by Pearse and Cole eliminates the reflux but still does not eliminate stricture formation at the anastomotic site.

The use of a rubber prosthesis for repair of the ducts was discarded because of the frequency of precipitation of bile salts with obstruction of its lumen. Sullivan's experiments with the repair over a rubber prosthesis resulted in the evolution of the T, or fishtail, tube which could be pulled out after a proper interval before precipitation of bile salts occurred but which frequently resulted in trauma to the repaired duct in its removal with resultant stricture formation.

The use of a vitallium tube by Pearse (13) seemed to eliminate this danger of obstruction and was enthusiastically used as a prosthesis for repair of defects in the ducts and for anastomotic procedures between cut ducts and bowel where the distal ampullary portion of the duct was not available. However, the fact that precipitation of bile salts and obstruction will occur in these tubes has been reported by

a number of authors. Pearse (13) in 1945, cited 12 cases of obstruction of 208 collected cases.

Neibling and Walters in 1947 obstructed vitallium tubes in which they were used. Neibling recommended the use of some prosthesis for repair which could be passed rather than one that was indefinitely in place.

The ideal prosthesis is one which is retained in place as long as desired to occur but which can be passed when time is over. Such a method is that reported by McArthur and reported by him as burying a catheter in the repaired duct. A long portion of the catheter is passed through the papilla into the duodenum; the constant duodenal tug upon the catheter gradually draws it into the intestine where it can be discharged per rectum. If it is wished to leave it a certain length of time, this is readily accomplished by tying a ligature to the catheter and anchoring it to the abdominal wall. The anchorage can be removed when desired and the catheter passed 3 to 7 weeks (Figs. 1 and 2).

In the 8 cases reported by McArthur in 1923 the shortest time in which the catheter was passed was 27 days and the longest was 3 months.

Repair over a buried tube was first reported by Jenckel in 1905. He put a catheter into the hepatic duct and buried the other end in the duodenum by the Witzel method. A fistula developed due to a tear in the tube, but healing occurred and was well 4½ years later.

De Graeuwe, Kehr, Voelcker, and Brewer reported cases by this method. In 1925, they had collected 24 successful cases. Three years after the first operation

Fig 1 Case 1 Repair of a simple transverse injury of the duct over a catheter

and 1 year after its publication, Sullivan reported successful operations upon 8 dogs

In 1912, Arnsperger and Kimura performed the Sullivan operation on dogs at the Wilms' clinic. The tube usually passed about the thirty-fifth day, but all of the animals developed stenosis at the duodenal junction of the new channel

Museneck, in 1926, operated upon a large number of dogs. Of 28 animals in which the Sullivan tube was used, 26 developed stenosis. In all, the duodenum was plastered up under the liver. In the 2 cases in which stenosis had not occurred, the tube had remained in place.

Halpern in his experiments found that epithelization of a defect did occur with little stenosis if ascending infection was minimal. However, ascending infection occurred in all but 5 of the 28 animals. He concluded that epithelization was more influenced by adequate blood supply than by the extent of the defect.

The present report adds the following 2 cases to the 8 reported by L. L. McArthur in 1923.

CASE 1 No. 304689 C. W., a white woman, aged 41 years, had cholecystectomy performed on July 6, 1934. A chronic cholecystitis with stones was found. There was one stone partially in the cystic duct. The cystic duct was markedly distorted and was dissected with difficulty. The common duct was accidentally severed, but the error recognized and a No. 10 F rubber catheter was buried

Fig 2 Case 2 Procedure used when the distal common duct was found to be completely obliterated

with one end well into the duodenum and the cut common duct repaired over it. She left the hospital at the end of 19 days with no bile drainage at the time of discharge. One and one-half months later she developed jaundice with diarrhea and abdominal pain for 4 days. Roentgen examination showed

Fig 3 Roentgenogram in Case 2 showing the position of catheter in repair of the common duct

about a 2 centimeter advancement of the tube from its position at the previous examination

The tube passed 17 weeks and 2 days after its insertion, not eroded and with the silk suture intact

In October, 1935, she complained of attacks of pain in the right upper quadrant and developed a mild jaundice which lasted 6 weeks, but which cleared spontaneously. Since then she has had no complaint

CASE 2 No 321299 A young colored woman, aged 27 years, had a cholecystectomy and common duct exploration performed December 30, 1935. The gall bladder was packed with stones and there was a tortuous common duct through which a probe could not be passed. Simple drainage of the duct was performed. At the end of the fourth week, the biliary fistula persisting, diodrast was injected, which showed a definite constriction of the ampulla.

She was readmitted May 11, 1936 with a profound jaundice. The fistula had closed spontaneously after 3 months. She was reoperated upon May 13, 1936. The strictured area was opened and a No. 10 F catheter passed well into the duodenum and the proximal end passed upward into the dilated common duct. Nine weeks after operation, the catheter passed (Fig. 3).

She remained free of symptoms for 5 months, then was readmitted with fever, chills, and jaundice. She was reoperated upon and at this time the duct was severed above the fibrous stricture and approximated to a new opening made in the duodenum just distal to the site of the normal papilla. Again the anastomosis was done over a buried catheter with anchoring of a black silk thread to the skin as before. Her convalescence was uneventful and she was discharged 3 weeks after operation. Six weeks post-operative, at the clinical meeting of the Chicago Surgical Society at St. Luke's Hospital, the anchoring stitch was cut and the catheter passed per rec-

tum 2 days later. This patient has reported for observation at frequent intervals since and to date has remained perfectly well.

CONCLUSION

A buried catheter which is passed by the intestinal tug upon its distal portion makes a satisfactory prosthesis for repair of short defects in the common duct. It can be retained as long as desired for healing to occur, but can be passed when that time is over.

SYNOVIAL OSTEOCHONDROMATOSIS

STANLEY M LEYDIG, M D, F A C S, and RICHARD T ODELL, M D, St Louis, Missouri

SYNOVIAL osteochondromatosis is a disease in which osteocartilaginous bodies develop in the synovial membrane and are extruded into the joint as loose bodies, or they may remain pedunculated and attached to the synovium. This condition usually occurs in the knee, but may occur in other joints, and in 1 of our cases the condition was found bilaterally in the elbows.

Synovial osteochondromatosis may be considered a benign neoplasm because it is an abnormal tissue growing without regular structure and because metastases do not occur.

In 1924 Jones reviewed the literature (5) and gave credit to Laennec for the first description of the condition in 1813.

Since the original observation there have been many opinions as to its etiology and histopathogenesis. Trauma and infection are factors in aggravation but are not thought to be primarily responsible. The reason for this report is to corroborate this theory, as in most of our cases the excitant factor of inflammation, or trauma, was obvious. In 1907 Lexer advanced the hypothesis that osteochondromatosis results from embryonal rests of the synovial membranes and suggested the similarity in development of cartilage and synovium (5). Geschickter states that the primitive connective tissue which exists normally in the synovium and at the point of reflexion of a normal joint capsule retains its power of forming both cartilage and bone. Persistence of strands of this connective tissue about the joints accounts for the cartilaginous and osseous masses found not only in osteochondromatosis, but in joint spurs, or osteophytes of chronic arthritis. Why such strands of embryonal connective tissue continue to exist in a completed joint structure is not clear. Neither is the mechanism understood of how trauma and infection may aggravate this type of con-

nective tissue, resulting in a condition which represents an overstimulation of a normal process (3).

The pathological findings grossly reveal many white cartilaginous spheroid bodies varying in size from flakes of $\frac{1}{2}$ to 1 inch in diameter, either free or attached to the synovium. They are located in the synovial folds and also in any communicating bursae of the joint. The bodies may be found grouped in masses so that they may be removed in 1 piece. The synovium is markedly thickened and quite vascular. Microscopically the osteocartilaginous body has a superficial layer of fibrous tissue beneath which is hyaline cartilage. In the center it is composed of calcified cartilage and frequently osseous tissue but may contain hyaline cartilage alone. Normally the synovial membrane is composed of an external layer, the stratum fibrosum, and an internal more cellular layer, the stratum synoviale (6). In these joints the stratum synoviale is edematous and thickened, and the bodies can be seen growing in the synovial stratum and appear to be migrating inward. They may remain pedunculated on the synovium until they become detached and extruded into the joint cavity. Phemister states the synovial fluid contains proteins and salts, and believes the irritation by these bodies might enrich the fluid and thus be a nutritive source for further growth of the detached bodies, as hyaline cartilage is almost devoid of blood supply and is thought to derive its nutrition from the synovial fluid. In the pedunculated or attached bodies the bone that is formed is normal, but in the loose bodies the bone becomes degenerated (7).

The diagnosis of synovial osteochondromatosis might be suspected from the history and physical examination, but the roentgenograms are usually quite characteristic and demonstrate the presence of the bodies if they are calcified or contain bone. However, if the bodies are entirely cartilaginous, the x-ray

From the Department of Surgery, Washington University School of Medicine, St Louis, Missouri.

Fig 1b

Fig 1 Case 1 a, Preoperative roentgenogram showing multiple loose osteocartilaginous bodies in the knee joint b, Gross appearance of the bodies c, Postoperative appearance 8 years later Two bodies in the posterior compartment were not removed but clinically did not cause symptoms These bodies have increased 5 times their apparent original size and now resemble the condition seen in Figures 5 and 6

between the ages of 30 and 50, although no age group is exempt, as in 1 case reported the age was 62 years (Rixford) It occurs more often in males, and affects the knee, elbow, ankle, hip, and shoulder in that order of frequency (3) The symptoms consist chiefly of pain and limitation of motion The pain is usually mild, and the patient often presents himself for treatment many years after noticing the first symptoms which resemble those of chronic hypertrophic arthritis A dull ache with limitation of motion, occasional locking and grating sensations together with a noticeable swelling of the affected joint are the usual complaints On examination the joint deformity is apparent and localized Crepitant masses may be palpated Tenderness over the joint is generalized

findings may be entirely negative The condition is seen in middle aged adults usually

Fig 2a

Fig 2b

Fig 2c

Fig 2 Case 2 a, Preoperative roentgenogram showing the osteocartilaginous bodies in the right elbow b, Gross appearance of bodies and resected head of radius c, Post-operative roentgenogram of elbow showing 1 loose body posterior to the coronoid process that caused symptoms and was subsequently removed d, Left elbow, same patient, showing a few loose bodies and the hypertrophied radial head

The treatment is surgical eradication of the loose bodies, followed by synovectomy and removal of adjacent bursae and their contents in so far as possible. Treatment by irradiation has not been described and would probably not be effective in a benign, slow growing lesion of this type. Recurrences have been seen following surgical removal, and subsequent sarcomatous change has been reported necessitating amputation (5).

Degenerative changes, which resemble those in hypertrophic arthritis, occur secondarily, and result in extensive lippling and overgrowth

Fig 2d

of bone at the joint margins. For this reason, a complete removal of the patella in addition to synovectomy was done in 1 case with knee involvement. In the elbow, the head of the radius was resected as it was hypertrophied and overgrown with osteocartilaginous tissue. Pronation and supination were markedly

Fig 3a

Fig 3 Case 3 a, Preoperative roentgenogram of right knee b, Appearance of synovium removed from same knee

Fig 3b

limited at operation until resection was done in addition to eradication of the synovial membrane and osteocartilaginous bodies.

We believe that the following cases illustrate the aggravation of synovial osteochondromatosis by infection as in Case 1 (Fig 1), and by trauma as in the remaining cases (Figs 2, 3, and 4).

Osteochondromatosis is not the same as osteoarthritic spurs, or osteophytes which have broken off and become loose bodies, many such cases may have been erroneously considered as chondromatosis. Figures 5 and 6 reveal such cases in which the bodies removed were calcified cartilaginous bodies but the synovial membrane was free from the pathological changes described.

CASE 1 (Figs 1a, 1b, and 1c) W. M., male, age 34 years, noted a gradual progressive stiffness of the left knee, beginning 6 years previously. Pain on active motion of the knee had been moderate and was more severe in attempting extension. No history of locking was given. The past history revealed no injury or infection and the family history was irrelevant.

On examination the left knee was found to be semiflexed, and attempts at active or passive motion were limited through an arc of 10 degrees and were painful. The left knee was warmer than the right and there was a slight tenderness over the posterior aspect of the knee and on either side of the patella. Laboratory findings disclosed a white blood count of 11,700, normal Schilling count, and urine negative. X-ray examination by Dr. E. W. Spinzig, radiologist of Lutheran hospital, revealed many opaque bodies lying in the anterior and posterior compartments of the knee joint with degenerative changes at the joint margins.

On June 19, 1940, the knee joint was opened anteriorly through a medial longitudinal incision, and the loose bodies were eradicated and a synovectomy was performed. Extensive osteocartilaginous tipping about the articular margins was removed, and since considerable encroachment of this overgrowth was noted about the patella, not only along the margins, but on the inferior surface, the patella was removed and also both semilunar cartilages. In order to eradicate the bodies in the posterior compartment, it was necessary to incise the anterior cruciate ligament which subsequently was sutured with silk. Sheet cotton and bandage dressing were applied, and active motion was encouraged on the eighth postoperative day although it caused some pain. The course was uneventful and the patient was discharged after a few weeks. Weight bearing was allowed at 6 weeks. He received physical therapy biweekly for 12 weeks.

Fig 4a

Fig 4b

Fig 4 Case 4 a, Preoperative roentgenogram of knee which was entirely negative b, Low power microscopic section showing cartilaginous nodule being formed in the synovia and others extruded into joint unattached c, High power microscopic section of a nodule with young cartilage cells and beginning calcification

with infra-red rays and massage as soon as he was discharged from the hospital. Re-examination after 2 years in August, 1942, showed a range of motion from 180 degrees to 80 degrees' flexion and in June, 1948, after 8 years motion from 180 degrees to 90 degrees which was entirely painless and there was no instability.

Fig 4c

CASE 2 (Figs 2a, 2b, 2c, and 2d) R. N., female, age 46 years, had noticed a progressive limitation of the right elbow with swelling and deformity. The patient attributed the cause to an injury which she said resulted in 2 broken elbows when she was 6 years old and she believed the right elbow had not healed properly. Because of such noticeable deformity she felt she could not wear short sleeves. The stiffness gradually progressed until she became unable to straighten the elbow or turn her wrist. Pain had been almost absent except occasionally when she felt a locking sensation. Examination revealed a deformity of the right elbow with a localized tumor posteriorly 1 inch proximal to the joint which was cystic and felt as though it contained loose buckshot. Extension was limited to 110 degrees and flexion to 90 degrees. There was crepitation on joint motion. Pronation and supination were limited at about 50 per cent and became very painful when motion was passively increased beyond this range. Laboratory findings were: white blood count 8,400, red blood count 4,700,000, calcium 7 milligrams, phosphorus 64, phosphatase 11. X-ray examination showed many opaque bodies lying in the olecranon bursa, and in the joint cavity together with hypertrophic changes about the head of the radius, which appeared hypertrophied. On August 31, 1942, the elbow was opened through a lateral incision over the head of the radius which was overgrown with cartilaginous tissue and appeared twice the normal size. Another incision was made on the medial side exposing a conglomerate mass of bodies in the posterior bursa which were re-

moved together with those in the medial part of the joint. The cavity was irrigated with saline through and through to wash out many tiny cartilaginous flakes. The synovial lining of the joint was removed as far as possible and also the bursal sac.

Motion was started actively on the sixth post-operative day. After 2 weeks, pronation and supination improved but was still limited by 30 per cent and the elbow extension was increased to 150 degrees and flexion to about 90 degrees and was only slightly painful. The postoperative course was complicated by a bleeding submucous myoma of the uterus which required gynecological intervention and surgery about 2 weeks postoperative. Otherwise there was an uneventful course so far as the arm was concerned. The motion was slightly improved and the patient was free of discomfort until 3 months later when several bodies, overlooked at the original operation, were palpated on the anterior lateral aspect of the arm. Under local anesthesia, exploration revealed the loose bodies behind the coronoid process. After several months motion was still markedly limited but the elbow remained free of pain.

CASE 3 J. E. D., male, age 65 years, had difficulty with his right knee for several years which cul-

Fig. 5 Osteocartilaginous bodies lying free in suprapatellar pouch; this is not a case of synovial osteochondromatosis, however.

Fig. 6 Similar to Figure 5 with osteocartilaginous bodies in posterior compartment and suprapatellar pouch without the synovial condition seen in osteochondromatosis.

Laboratory findings were 10,150, red blood count 3,770,000, hemoglobin, 14.1, urinalysis, negative, Kahn, negative, hemogram—basophils, 2, eosinophils, 2, juveniles, 1, segmented lymphocytes, 23, monocytes 8, no sedimentation rate determination.

A medial parapatellar incision was made upon operation and a small amount of viscid clear yellow fluid escaped. The synovium was studded with small cartilaginous bodies. Patellectomy and posterior and anterior synovectomy were performed.

Postoperative course was uneventful.

Chronic inflammation of the synovial membrane with some fibrocartilage was found upon microscopic examination. The lining showed nodular fibrosis. The nodules of the synovial membrane revealed fibrosis, connective tissue with formation of cartilage, and, in the center of some of these, areas of bone formation.

CASE 4 F L The patient had a painful knee for 4 years following a blow on his right knee when it bumped on a ladder rung. Seven to 8 months after the injury the right knee became increasingly stiff and painful. He then noted on movement the sensation of something being loose in the joint, and the pain in the knee had become a constant dull ache relieved a little by exercise. He was advised that he had arthritis and for 6 months before admission to the Washington University Clinics received physical therapy without benefit.

Examination of the right knee revealed it to be swollen, not hot or red, or excessively tender. On motion there was soft crepitus, flexion was not limited but extension lacked 5 degrees of normal. On palpation the suprapatellar pouch was bulging and transmitted a gritty mush feeling. Some slight tenderness was noted over the entire joint.

X-ray examination revealed no pathological process in the knee.

Laboratory findings revealed normal urine and the blood count showed red blood cells 4,750,000, white blood count 8,750, hemoglobin 14.5, hemogram—eosinophils 1, stab, 3, segmented, 68, lymphocytes 25, monocytes 3, Kahn, negative.

The patient's knee was explored through a medial parapatellar incision. The bulging capsule was opened which allowed the incision to become filled with a double handful of fine granules of cartilage about the size of rice grains. There was no free fluid. The synovium was shaggy and thickened and slightly reddened. The articular cartilage of the tibia was thin in several areas. The wound was irrigated and a partial synovectomy including medial meniscectomy was done.

Postoperative course was uneventful except for an accumulation of fluid which required aspiration on the ninth day and 85 cubic centimeters of old blood was removed.

The patient was able to go to work 6 weeks after operation and at that time there was no swelling or limitation of motion of the knee.

Microscopic examination of the synovial membrane revealed numerous small villous processes which were undergoing metaplasia into cartilage. In some areas calcification of this hyaline cartilage was seen (Figs 4b, 4c, and 4d).

SUMMARY AND CONCLUSIONS

1 Synovial osteochondromatosis is a rare affection of the synovial membrane of joints leading to the formation, by the synovium, of cartilaginous or osteocartilaginous bodies. This process may be considered a benign neoplasm because the bodies continue to be formed and grow but they do not metastasize.

2 Infection and trauma play an excitant role and must be considered definite etiological factors in the production of synovial osteochondromatosis.

3 Synovial osteochondromatosis should not be confused with the much more common loose body or joint mouse.

4 Therapy consists of surgical removal of the bodies and synovectomy.

5 Case reports have been presented.

THE TECHNIQUE OF GASTRIC RESECTION FOR PEPTIC ULCER

G GAVIN MILLER, M.D., F.A.C.S., and CHARLES B. RIPSTEIN, M.D., Montreal, Canada

IN recent years, much controversy has centered about the surgical treatment of peptic ulcer. Dragstedt and his co-workers have advocated vagotomy as the operation of choice but the consensus appears to be that subtotal gastrectomy offers the best chance of cure with a minimum of undesirable after effects (6). In our own experience this has certainly been the case. In a series of 1,000 resections by one of the authors (GGM) in the past 12 years we have been struck by the smooth postoperative course, the low mortality, and the excellent end-results. This series is being analyzed at present and will be the subject of a further communication.

The operative technique of gastric resection has changed over the years as new difficulties have been met and solved. In its present form it represents a routine which is easily adapted to the conditions encountered in any individual case. The purpose of this paper is to describe the operation in detail pointing out the common difficulties and the means of obviating them.

PREOPERATIVE PREPARATION

The state of nutrition is the major preoperative problem in ulcer patients. These individuals have often been on inadequate diets and this deficiency may be aggravated by bleeding or pyloric obstruction. Routine plasma protein and hemoglobin determinations are carried out and operation is postponed until all deficiencies have been corrected.

If pyloric obstruction is a prominent feature and the stomach is atonic and dilated, it is necessary to keep it empty by constant suction for 48 hours before operation. This method permits the gastric wall to regain its tone and decreases edema. In cases of non-obstruction a Levine tube is passed the morn-

ing of operation and suction is applied during the procedure. The tube is left in place 12 to 24 hours postoperatively. This step is not essential but we feel that it is beneficial in the prevention of distention and in the removal of blood and secretions from the gastric stump. The tube is not allowed to cross the anastomosis because of the possibility of pressure necrosis.

Blood transfusion is used in cases in which the hemoglobin is below normal or in which there has been recent bleeding.

OPERATIVE TECHNIQUE

High spinal anesthesia with nupercaine 1:1,500 has proved to be ideal. The operation can usually be completed in less than 2 hours and there is adequate relaxation for closure. Heavy preoperative sedation is used and in occasional cases a slow pentothal drip is given to supplement the spinal anesthesia.

The abdomen is opened through a midline epigastric incision extending from the xiphoid to the umbilicus. Excellent exposure is thus obtained for all stages of the operation and the need for strong retraction is minimized. In addition, since this incision goes through the fibrous linea alba it is relatively avascular and permits a strong closure. The incidence of postoperative wound complications has been very low with this approach.

Abdominal exploration is done and when the diagnosis has been confirmed the subtotal resection is carried out in the following steps:

1 (Fig. 1) The transverse colon is lifted up and a vertical incision is made in the mesocolon 1 inch to the left of the ligament of Treitz; care is used to avoid the midcolic artery. The right and left edges of this slit are marked with silk sutures.

The jejunum is then marked with another suture at a point 6 inches from the duodeno-jejunal junction and the colon and small bowel are returned into the abdomen. This step is

Fig 1

Fig 2

carried out first to avoid the undue handling of the bowel at a later stage after the stomach has been cut across and the peritoneal cavity has been exposed to potential soiling

2 (Fig 2) The greater curvature of the stomach is freed by the clamping and division of the individual vessels and their ligation with fine silk. The marginal vessel is left intact on the omental side, to avoid compromising the circulation of the great omentum. This mobilization is carried out from the pylorus to the bare area just distal to the vasa brevia.

3 (Fig 3) The operator's finger can then be passed around the stomach through the avascular part of the lesser omentum $\frac{1}{2}$ inch above the pylorus, and a tape passed through this opening is then used for traction.

The right gastric artery is isolated below the tape, divided between clamps, and ligated.

4 (Fig 4) The duodenum is freed from the surrounding structures by sharp scissor dissection. If the ulcer can be removed easily this is done and the duodenum is divided below the lesion. In such cases the McClure modification of the Furness clamp is used and the duodenal stump is inverted with a continuous Lembert stitch of No 000 chromic catgut. This suture is reinforced with a layer of interrupted fine silk sutures and the stump is

then buried into the capsule of the pancreas and covered with omentum held in place with fine silk sutures. In cases with a large, caloused, adherent, penetrating ulcer a different technique is used. In the past, great difficulty was encountered in the freeing of these ulcers from the pancreas and other organs. There is serious danger of injuring important structures in performing this dissection and it is difficult to free sufficient duodenum to obtain a satisfactory closure. In an attempt to solve

Fig 3

Fig 7

entire lesser curvature, excising about 75 per cent of the stomach as a routine measure. The lesser curvature half of the cut edge is then turned in with 2 layers of interrupted fine cotton, $1\frac{1}{2}$ inches is left for the anastomosis (Fig 7). The left edge of the opening in the mesocolon is sutured to the posterior wall of the stomach and the jejunum is brought up through the opening and a retrocolic no-loop antiperistaltic anastomosis is carried out. The seromuscular layer is sutured with interrupted fine cotton and the mucosal layer is sutured with continuous No 000 chromic catgut, a lock stitch being used posteriorly and a baseball stitch anteriorly. The jejunum is fixed along the lesser curvature with 2 purse string sutures to form a Hofmeister valve. This step prevents reflux of gastric contents along the afferent loop and protects the so-called "dangerous angle" of the anastomosis (Fig 8). The right edge of the mesocolic opening is then sutured to the anterior wall of the stomach.

9 The abdomen is closed with interrupted medium steel wire sutures in peritoneum, fascia, and skin.

POSTOPERATIVE CARE

Continuous gastric suction is maintained for 24 hours, and water is allowed by mouth

Fig 8

to wash any old blood from the stomach. On the first postoperative day the tube is removed and the patient is allowed up. The following feeding routine has been used with complete satisfaction.

First day

One ounce of water hourly

Second day

One ounce of water and 1 ounce of milk hourly

Third day

8 00 a m Five ounces of tea

10 00 a m Three ounces of water and 2 ounces of milk

12 noon Five ounces of clear soup

anastomosis of jejunum to stomach

Fig 9

2 00 p m Three ounces of water and 2 ounces of milk

4 00 p m Five ounces of albumen water

6 00 p m Five ounces of tea

8 00 p m Three ounces of water and 2 ounces of milk

Fourth day

8 00 a m Tea, bread and butter

10 00 a m Orange juice

12 noon Clear soup and custard

2 00 p m Orange juice

4 00 p m Soft boiled egg, bread and butter, and tea

6 00 p m Bread and butter, jelly, and tea

8 00 p m Orange juice

Fifth day

Soft diet with extra feedings at 10 00 a m, 2 00 p m, and 8 00 p m. Fluids as tolerated

Sixth day Same as fifth day

Seventh day

Bland ulcer diet with extra feedings at 10 00 a m, 2 00 p m, and 8 00 p m

This routine is supplemented by intravenous infusions for 48 hours, 3,000 cubic centimeters are given daily consisting of 1,000 cubic centimeters of 5 per cent glucose saline, 1,000 cubic centimeters of parenamine, and 1,000 cubic centimeters of 10 per cent glucose in water. Vitamins B and C in soluble form are given with this routine. The sutures are removed on the 8th day and the patient leaves

the hospital on the 10th day on a convalescent ulcer diet. This diet is usually maintained for 2 or 3 months, at the end of which time all restrictions are removed.

SUMMARY

1 A technique of gastric resection for peptic ulcer is described. The essential features are as follows: (a) midline epigastric incision, (b) removal of 75 per cent of the stomach, (c) removal of the pylorus in all cases, (d) a simplified method of duodenal closure in large callous ulcers, (e) a retrocolic, no loop, antiperistaltic anastomosis, according to the Hofmeister-Finsterer technique, is made.

2 The preoperative and postoperative care of ulcer patients is outlined.

PREDISPOSING ACTION OF ANESTHETIC AGENTS ON THE VASCULAR RESPONSES IN HEMORRHAGIC SHOCK

B W ZWEIFACH, Ph D, and S G HERSHEY, M D, New York, New York

RECENT work on experimental shock (5) has clearly established the existence of a variety of initiating and sustaining mechanisms which lead to peripheral circulatory collapse. Among the mechanisms reported to participate in the syndrome are a reduced blood volume via extravascular fluid loss (1), compensatory and decompensatory changes in the peripheral blood vessels via humoral principles (11, 13), neurogenic vasoconstrictor influences (4), and endothelial toxins of tissue and bacterial origin (3, 8). These different mechanisms do not consistently appear in the same sequence relative to one another, nor do they participate to the same degree in different subjects or in different types of shock. The precise experimental conditions under which the shock is produced appear to determine which of the several possible factors will predominate and which of them will be excluded. One of the major determinants of the character of the shock syndrome has been shown to be the type of anesthetic agent employed (12). The influence of the anesthetic agent on the course of the syndrome was found to be exerted in a specific, predictable manner. The specific vascular effects of different anesthetic drugs were such as to make it possible to produce a different sequence in the peripheral circulatory reactions under otherwise identical experimental procedures. Certain anesthetics, such as cyclopropane and morphine, accentuated the compensatory vasoconstrictor aspects of the syndrome virtually to the exclusion of other factors. Other agents, such as sodium pentobarbital and pentothal, aggravated the reduced, circulating volume by depressing the compensatory responses of the peripheral blood vessels. Finally, agents such as ether

produced sufficient vascular dilation and endothelial damage to limit severely the compensatory vascular phenomena and to lead to a disruption and stasis of the peripheral circulation early in the syndrome. In the present study, use was made of the predisposing actions of three different anesthetic agents: cyclopropane as an agent favoring a predominantly compensatory response to hemorrhage, ether to demonstrate an extreme decompensatory pattern, and sodium pentobarbital to provide an intermediate pattern. The specific properties of these three anesthetic agents made it possible to study selectively several of the basic mechanisms participating in the syndrome.

Chambers, Zweifach, and associates (13) were able by direct visualization of the small blood vessels to follow the progression of shock following hemorrhage on the basis of characteristic alterations in the functional response of the capillary bed. Two patterns of response were noted: (a) an initial period of compensatory activity in which the peripheral vascular apparatus accommodates its capacity and vasomotor activity to the reduced blood volume, (b) a subsequent decompensatory period in which the capillary bed loses its ability to restrict effectively the circulation in a manner compatible with tissue needs, as a result of which adequate venous return into the general circulation is no longer possible. The decompensatory phase was associated with the development of the so-called "irreversible" stage of shock. Both the compensatory and decompensatory phases were shown to be related to blood-borne principles (vasoexcitor principle, VEM, and vasodepressor principle, VDM). Although these studies made no direct evaluation of the role of the nervous system in the reactions of the peripheral blood vessels to blood loss, it was clear from subsequent experiments on animals subjected to postganglionic sympathectomy that vasoconstriction of

the larger vessels during the compensatory stage could, in large part, be ascribed to increased neurogenic stimuli. Increased reactivity of the terminal arterioles and precapillaries, on the other hand, was related to a blood-borne vasoconstrictor principle, VEM, of renal origin (6). The decompensatory stage did not appear to be related to a failure of neurogenic vasoconstrictor influences but to an interference with the response of the peripheral blood vessels to these stimuli by the progressive accumulation in the blood stream of a vasodepressor principle, VDM, principally of hepatic origin (6).

The effectiveness and widespread use of blood replacement therapy has tended to over-emphasize the fluid loss aspect of the syndrome and has led to the clinical neglect of other mechanisms which exert a deleterious influence on the blood vessels themselves (7). Further clarification of the mechanisms leading to the decompensatory phase could be of considerable value in counteracting the progressive refractoriness to corrective therapy which develops during this stage of shock. The present report is therefore concerned particularly with the changes in the peripheral blood vessels, observed by direct microscopic study, as they reflect the influence of anesthetic drugs on the decompensatory, hyporeactive phase of the shock syndrome.

MATERIAL AND METHOD

Alterations in the peripheral circulation were studied visually in the omentum of a dog by a technique previously described (10). It consists essentially of the exteriorization of the omentum into a rubber sheath with a small portion of the tissue resting in a special moist chamber. The omental tissue was irrigated with a thermostatically controlled, warm solution of Ringer gelatin at pH 7.3 having the colloidal osmotic pressure of a serous exudate. This method of preparation allowed for normal reactivity of the vascular bed for a period in excess of 5 to 6 hours.

The bleeding procedure consisted of an initial blood loss of 2 per cent body weight and subsequent small bleedings (0.5-0.2 per cent) at 15 to 20 minute intervals. These were continued until the flow in the larger omental ar-

teries became static during the actual bleeding procedure. This degree of blood loss usually corresponded to the amounts required to induce fatal shock. Cyclopropane and ether were given with excess oxygen through an endotracheal catheter by a closed to-and-fro rebreathing system providing for carbon dioxide absorption. The first plane of surgical anesthesia was maintained throughout. Sodium pentobarbital was injected intravenously as a single dose of 25 milligrams per kilogram of body weight. The animals received no other medication. Continuous visual records of the circulation were obtained in selected animals by photomicrography. In several instances motion picture records were made. The illustrations included in the present paper represent individual frames from such a continuous film or selected photomicrographs.

A number of criteria were routinely employed for evaluating the functional state of the peripheral vascular bed: (1) degree of vasoconstriction, (2) rate of blood flow, (3) extent of ischemia in capillary bed as estimated by the number of active capillaries, (4) reactivity of arterioles and precapillaries to epinephrine applied topically, (5) evidence of capillary stasis or increased permeability, (6) presence in blood of vasoactive substances as demonstrated by the rat mesoappendix assay (10). In the accompanying photographs it is possible to demonstrate only the vasoconstrictor changes, the development of either capillary ischemia or hyperemia, and the presence or absence of capillary stasis.

EXPERIMENTAL RESULTS

The data are presented under three categories according to the nature of the vascular response following hemorrhage. In each category are presented selected protocols in the form of photographs indicating the sequence of hemodynamic changes in the capillary circulation characteristic of this group of animals.

1. Compensatory type of vascular response
Of a series of 30 dogs subjected to hemorrhagic shock during cyclopropane anesthesia, 26 animals went into fatal circulatory collapse while showing a purely compensatory sequence of vascular changes throughout the syndrome. Table I presents the pertinent data on Dog

No 12 which is typical for this category. Accompanying this is Figure 1 which illustrates the vascular changes as observed through the microscope. In order to indicate the terminology of the different vascular components a schematized tracing of the capillary bed is included in Figure 1,a as a point of reference for the ensuing photographs.

The small arteries and arterioles (50 to 60 micra) undergo a progressive vasoconstriction with the successive bleedings. The vasoconstriction becomes clearly evident at 3 per cent blood loss in Figure 1,d and is pronounced in the latter stages (40 per cent) (Fig 1,e). Often at exitus (Fig 1,f) the arteries and arterioles are almost completely constricted and empty of blood.

The precapillary sphincters show an increase in vasomotion which results in a periodic reduction in blood flow through the capillary bed. The augmented vasomotion is pronounced after 3 to 4 per cent blood loss (Fig 1,d) the precapillaries remaining in a constricted state for a greater proportion of the cycle. The compensatory type of vascular response with marked narrowing of the precapillary vessels is clearly seen in Figure 1,e and is still present in Figure 1,f, taken just prior to circulatory collapse.

Initially there is an active blood flow through most of the capillary vessels (Fig 1, b). With successive bleedings the active circulation is progressively restricted to fewer capillaries (Fig 1,d and e). When maximal blood loss has been attained, little or no active circulation is present in the majority of the capillary vessels (Fig 1,e). At exitus (Fig 1, f) the capillary network is highly ischemic, the endothelial walls being visible only at the venous end where they join the collecting venules.

Only slight changes in caliber occur in the collecting venules, which have a sparse distribution of muscle in their walls. The darker appearance of the venules in the photographs as shock progresses is due to the slowed circulation and close packing of the red blood cells (Fig 1,d and e). At exitus (Fig 1,f) the venules are the only capillary vessels with blood.

Thus when profound shock develops in dogs bled during cyclopropane administration, the

arteries are partially narrowed, the arterioles are maximally constricted almost to the point of obliteration of the vessel lumen, the precapillary sphincters are closed, the capillaries are empty except for occasional blood cells, and only the venules contain stagnant blood.

2 *Intermediate type of vascular response* To illustrate this type of vascular behavior following hemorrhage, a protocol is given for Dog No 3 which was subjected to hemorrhage during sodium pentobarbital anesthesia. In this animal, 46 per cent of body weight was bled to produce fatal circulatory collapse (see Table II). The sequence of vascular changes is illustrated in Figure 2.

With a blood loss of only 2 to 3 per cent of body weight, a narrowing of the larger arteries and arterioles occurs (Fig 2 d). When sufficient blood has been withdrawn to lower the blood pressure below 45 millimeters of mercury, both the larger arteries and veins undergo more pronounced vasoconstriction (Fig 2,

e) At exitus (Fig 2,f) the arteries are constricted, but not as completely as in those animals bled during cyclopropane anesthesia.

An increase in activity of the precapillary sphincters occurred after blood loss of 3 per cent when the blood pressure was between 60 to 70 millimeters of mercury. The increased vasomotion markedly reduces the capillary circulation during the initial stages (Fig 2,d and e). However, the increased vasomotor activity does not persist, as can be seen in Figure 2,f. The capillary bed remains only partially ischemic (Fig 2,e) and actually has begun to open up with the approach of circulatory collapse (Fig 2,f).

The collecting venules at first show only a pronounced slowing of flow through them, with some evidence of clumping of red cells (Fig 2,d). No significant venular vasoconstriction is evident. As the shock deepens, the outflow from the collecting venules into the larger veins is almost completely curtailed (Fig 2,e). As a result, blood accumulates in the venules which then become somewhat engorged (Fig 2,f). At exitus there is no forward propulsion of blood in these vessels.

Thus, fatal circulatory collapse in dogs bled during pentobarbital anesthesia occurs with the arteries and veins narrowed, the terminal arterioles only partially constricted, many of the precapillary sphincters relaxed so that blood is present in the capillary vessels, and the venules congested and often distended.

3 *Decompensatory type of vascular response*
This type of vascular behavior was frequently seen in dogs subjected to hemorrhage during

ether anesthesia (15 dogs). Figure 3 contains a series of photographs taken of Dog No 64 and illustrates the extreme decompensatory changes which occur in the peripheral blood vessels in this group of animals. Fatal circulatory collapse was induced in Dog No 64 by a blood loss of 4.1 per cent of body weight (see Table III). The peripheral blood flow was already slowed when only 3.5 per cent of body weight of blood had been removed (Fig 3,d). At this stage the larger arteries were only moderately constricted (Fig 3,d). In the terminal stages, the arterioles are not at all constricted and show no forward propulsion of blood, the cells being clumped with intervening areas of clear plasma (Fig 3,f). The large veins showed little or no change in caliber throughout.

The precapillary sphincters showed evidence of an increased vasomotion when as little as 2 per cent of blood had been withdrawn (Fig 3, c). As can be seen in Fig 3,d and e the capillary bed does not become appreciably ischemic. Although less blood is circulating through the capillary vessels, none of the capillaries in the field are actually closed off (Fig 3, c, d, e). As a result, the blood flow in the collecting venules becomes sluggish when the blood pressure has fallen only to 60 to 70 millimeters of mercury. This is in contrast to the active venular circulation at a comparable stage of hemorrhagic hypotension in unanesthetized dogs, or dogs receiving cyclopropane anesthesia.

The collecting venules become engorged with blood and stasis develops about 30 to 40 minutes before circulatory collapse occurs (Fig 3,e). Many of the capillary channels are filled with blood which is closely packed (Fig 3,f). This type of stasis is usually associated with a loss of fluid into the tissues and is probably indicative of an increased capillary permeability.

The vascular picture in fatal hemorrhagic shock in dogs during ether anesthesia therefore occurs with moderate vasoconstriction of the larger blood vessels, a relaxation of the arterioles, an opening up of the precapillary sphincters, a trapping of blood in the capillary vessels and a pronounced engorgement of the venules with considerable extravasation in

Fig 1 Hemorrhage during cyclopropane anesthesia compensatory type of vascular response a, In order to indicate the terminology of vascular components, a schematized tracing of capillary bed is given arteriole, *Arte*, pre-

capillary sphincter, *Precaps*, capillary bed, *Cap bed*, collecting venule, *Venule* b to f, Successive stages illustrating vascular changes during progression of shock syndrome in the omentum of dog $\times 50$

many of these vessels. This group of animals not only showed the most pronounced degree of vascular change but was also refractory to blood replacement therapy.

Blood-borne principles Our previous experiments (11) have indicated that the vascular changes observed in the omentum during shock are closely paralleled by the appearance in the blood stream of two vasotropic principles whose vascular effects were comparable to those observed in the shocked animal at the time the blood samples were withdrawn for bioassay. In the initial, compensatory stage there appears a vasoexcitor principle, VEM,

which in the test rat potentiated the response of the terminal arterioles to epinephrine. In the latter stages of shock when decompensatory phenomena preponderate, a vasodepressor principle, VDM, appears in the blood which makes the terminal arterioles of the test rat refractory to the vasoconstrictor effects of epinephrine. In dogs subjected to hemorrhage with cyclopropane large amounts of the vasoexcitor principle appear in the blood and persist throughout the syndrome. In dogs bled with sodium pentobarbital anesthesia showing an intermediate type of vascular response, vasoexcitor material, VEM, appears in the

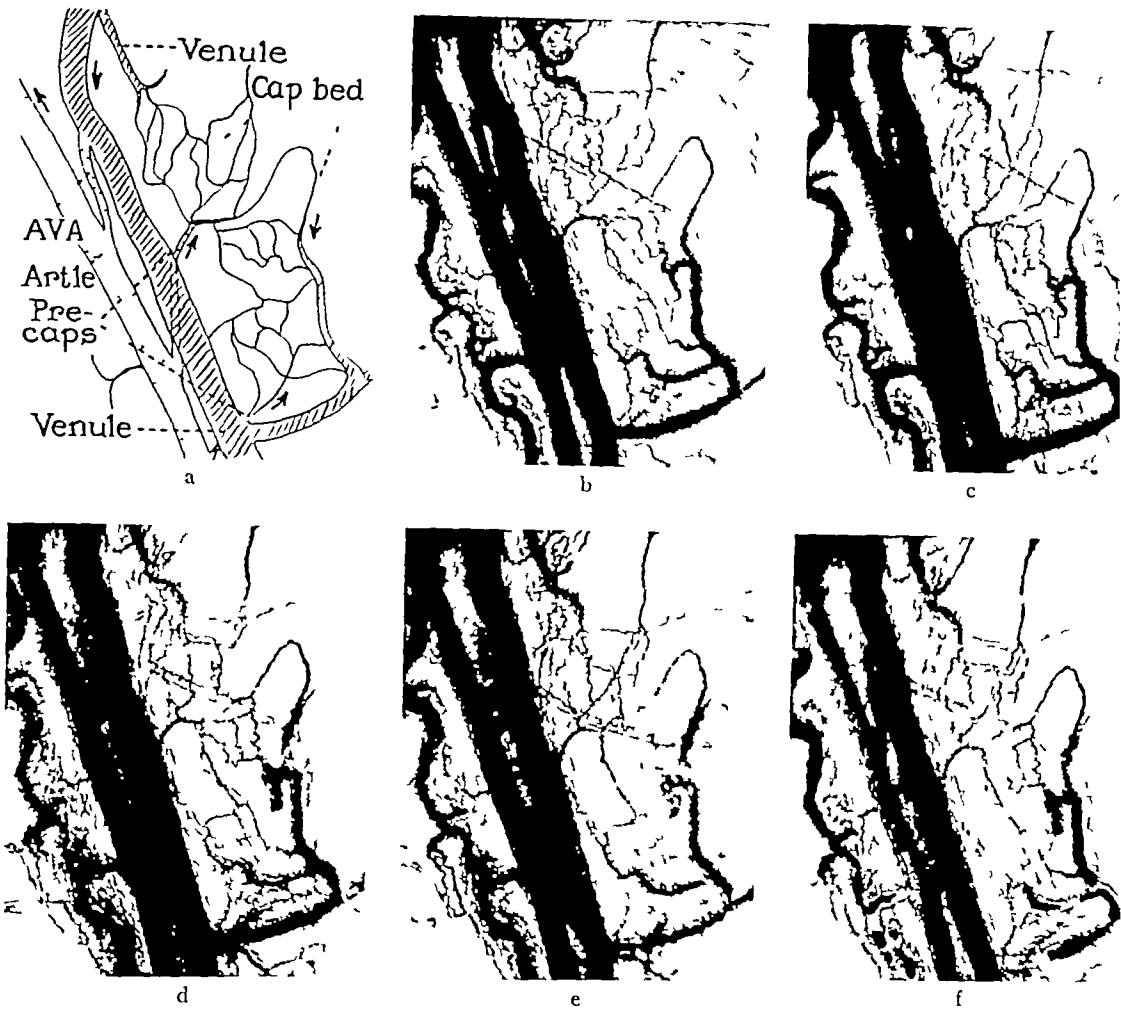

Fig 2 Hemorrhage during pentobarbital anesthesia, intermediate type of vascular response a, Abbreviations

same as in Figure 1 Note 4 1 4 (arteriovenous anastomosis) between arteriole and venule $\times 50$

blood stream early in the syndrome and is subsequently replaced by the vasodepressor principle which then persists until the animal goes into fatal circulatory collapse. In ether treated dogs showing a decompensatory type of vascular response, VEM appears in the blood stream only transiently and is soon replaced by the vasodepressor principle which is present at exitus in excessive amounts.

Anesthesia administered during shock The deleterious influence of anesthetic agents on the response of the peripheral vascular system to shock is evident from experiments in which anesthetic drugs are administered after shock has developed (2). This was most pronounced

in dogs bled during ether or pentobarbital anesthesia and to a lesser degree in dogs bled after morphine administration.

The subsequent intravenous injection of pentobarbital (2 to 3 mgm /kgm) during the period of drastic hypotension (40 to 50 mm Hg) which developed 4 to 5 hours after the initial induction of pentobarbital anesthesia was extremely hazardous, in 7 out of 10 animals, it resulted in a further marked deterioration of the capillary circulation. Frequently the terminal arterioles and precapillaries became dilated within a few minutes after injection. Reactivity of blood vessels to epinephrine also began to decline precipitously

Fig 3 Hemorrhage during ether anesthesia, decompensatory type of vascular response b to f, Illustrate the

extreme decompensatory changes in peripheral blood vessels $\times 50$

In dogs maintained with ether anesthesia it was invariably necessary during the progression of shock to discontinue the administration of ether and use only oxygen in the closed endotracheal anesthesia system. The addition of minimal amounts of ether to the oxygen mixture during profound shock resulted in the rapid dilatation of the small arterioles and a pronounced slowing of capillary flow. The venous circulation became almost stagnant.

In morphine treated dogs, the subsequent intravenous injection of morphine (1 to 5 mgm/kgm) during the period of drastic hypotension, produced in 2 out of 4 dogs a gradual slowing of capillary flow and a slow depression

of blood pressure which could be alleviated only by transfusion. These amounts of morphine were relatively innocuous when given to unbled dogs. The administration of morphine was also found to be deleterious when it was given to shocked dogs after the original blood volume had been restored with whole blood and the blood pressure had returned to approximately normal levels. In 1 dog, No 58, which had been anesthetized with sodium pentobarbital and had been in extreme hypotension for over $4\frac{1}{2}$ hours, the infusion of blood restored the blood pressure to 95 to 110 millimeters of mercury. Forty-five minutes after the infusion, the administration of 1

milligram per kilogram of morphine to this dog depressed the peripheral circulation within 5 minutes and almost immediately lowered the blood pressure to 50 millimeters of mercury. Deleterious effects of anesthetics administered during the shock syndrome were less severe in unanesthetized dogs, or in dogs given cyclopropane. However, even in these animals, extreme care had to be observed when anesthetics were administered once shock had developed.

DISCUSSION

The feature which distinguishes the shock syndrome is a considerable reduction in peripheral circulation. In most instances the circulatory insufficiency cannot be attributed to any single factor exclusively. With hemorrhage it is possible to produce a predictable syndrome in which the initiating factor is experimentally defined. The response of the peripheral vascular system to hemorrhage represents an attempt to accommodate the vascular bed to the reduced blood volume without curtailing the blood flow beyond the minimal requirements of the tissue. This is accomplished by a partial vasoconstriction of the larger arteries and veins, by an increased vasomotion of the terminal arterioles, and by an increased reactivity of the small blood vessels to humoral agents. Following a single massive, fatal blood loss the resulting vasoconstriction of the larger blood vessels is carried to an extreme. The effect is to curtail excessively the circulation in the tissues to an extent that appreciable quantities of blood are trapped on the capillaries and collecting venules. This might be termed an overcompensation productive of an unfavorable situation. With a graded type of bleeding, in which fatal amounts of blood are withdrawn over a period of 30 to 90 minutes, there is sufficient time for a compensatory hyperreactivity of the capillary bed to develop and thereby to assist in emptying the capillary bed. This compensatory ischemia was most pronounced in unanesthetized dogs subjected to hemorrhage.

An evaluation of the circulatory data from the viewpoint of anesthesia has demonstrated striking differences not only between the reactions of dogs subjected to hemorrhagic hypo-

tension with and without anesthesia, but between dogs bled while under the influence of different anesthetic agents. The predisposing action of anesthetics was readily apparent on the basis of the vascular changes observed through the microscope in the omentum of the dog.

In general, three categories of vascular response were observed with hemorrhage as the initiating factor. The first is the purely compensatory type obtained in unanesthetized animals and most closely approximated in the anesthetized group by those animals bled during cyclopropane administration. Under such conditions the capillary bed as an organic unit shows no essential dysfunction. When it occurs, circulatory collapse is essentially a mechanical failure of blood to be returned from the tissues as the result of excessive vasoconstriction of the larger blood vessels.

The second or intermediate type of vascular response was obtained with animals subjected to graded hemorrhage in which the hypotension is maintained for an extended period usually 3 to 4 hours with blood pressures below 40 to 50 millimeters of mercury. In these animals, although vasoconstriction of the larger blood vessels is relatively unimpaired, there progressively develops a physiologic derangement of the peripheral circulation. Capillary ischemia is no longer complete and a trapping of blood is evident on the venous side of the bed especially in the collecting venules. This type of response is seen most frequently in animals bled during sodium pentobarbital or morphine (2) anesthesia. The circulatory collapse is not solely a mechanical one since biochemical changes occur in the tissues and result in the appearance in the blood of decompensatory vasotropic principles.

The third or more toxic type of vascular change was obtained when ether was used as the anesthetic agent. In these animals not only were the compensatory responses of the capillary vessels severely curtailed but the vasoconstriction of the larger arteries and veins was not as pronounced as in animals anesthetized with other agents. In addition, this was the only anesthetic agent in which many animals showed signs of increased capillary permeability, with considerable capillary

stasis, extravasation, and visible evidence of hemoconcentration in the collecting venules

It is interesting to note that the three types of vascular response to hemorrhage are correlated with the prognosis for the effectiveness of therapy in each group (9). Animals showing no functional derangement of the peripheral blood vessels readily recover after fluid replacement therapy. The second or intermediate type of vascular response is associated with a progressive refractiveness to blood replacement therapy. The third type of vascular response is associated with an extremely poor response to similar therapy. It is also noteworthy that there is a comparable correlation in these three types of vascular response with regard to the ability to tolerate blood loss.

Under normal conditions there exists a precisely controlled relationship between the volume of circulating blood and the capacity of the vascular bed in which it is contained. Two fundamentally different mechanisms can disrupt this normal hemodynamic equilibrium. Peripheral circulatory collapse may be induced either by decreasing the volume of blood through hemorrhage or by increasing the capacity of the vascular bed through peripheral insufficiency. Both of these factors contribute to some extent to all types of shock. Under ordinary circumstances, it is difficult to predict the extent to which each of these two mechanisms participate. The observation that following uncomplicated hemorrhage, different anesthetic drugs, of themselves serve to emphasize the pattern of the vascular disturb-

ance by shifting it to one or the other extreme, would seem to offer further evidence that both mechanisms operate to some degree in all types of shock.

SUMMARY AND CONCLUSIONS

This report deals with the specific effects of anesthetic agents on the response of the peripheral blood vessels to blood loss. The data indicate that irrespective of the initiating factor, the compensatory responses of the peripheral blood vessels can be altered in a predictable manner, according to the anesthetic agent employed. The multifacet character of the shock syndrome is re-emphasized.

CYTOLOGICAL DIAGNOSIS OF CANCER IN TRANSUDATES AND EXUDATES

A Comparison of the Papanicolaou Method and the Paraffin Block Technique

EDWARD SATTENSPIEL, M D, Jersey City, New Jersey

ATTEMPTS at diagnosing cancer from study of smears of ascitic fluid date back to the middle of the last century, at which time dried smears were examined under the microscope for the first time with the express purpose of demonstrating the presence of cancer cells. These early efforts, however, were not very successful for the reason that cellular structures in a dried preparation are distorted and because there were not then adequate cellular criteria on which to base a diagnosis. The earliest significant advance came in 1895 with the publication by Bahrenberg of a description of the method of centrifugating fluid, of fixing the sediment and embedding it in paraffin, subsequently of cutting and staining the specimens in routine manner. Unfortunately, this article was buried in a rather obscure medical journal, with the result that major credit for the development and publicizing of the paraffin method has been ascribed to Mandelbaum, who began such work in New York in 1900 and published a large series of cases of metastatic cancer so diagnosed in 1917. This report stimulated, throughout the country, immediate interest in and enthusiasm for the technique, and the method was taken up in many different centers.

In 1928, in an excellent report, Zemansky thoroughly reviewed all the investigative work that had been done previously in this field and reported as well a large series of cases collected by himself. He concluded that the examination of pleural and peritoneal fluids for tumor cells was a valuable routine laboratory procedure, that a positive report should carry a high degree of accuracy, al-

though a negative report should be interpreted as any other negative laboratory report as not ruling out the presence of cancer. He felt that, with proper technical care, about 50 per cent of the cases of cancer with effusion could be diagnosed by this method alone. In approximately one-third of the positive cases he was able to state accurately the type of tumor involved and that the finding of carcinoma was twice as likely as sarcoma in an equal number of cases compared. He noted, then, that atypical mesothelial cells of long standing, as for example in ascitic fluid with associated cirrhosis of the liver, provide a source of error to the most experienced examiner, which fact has been well borne out by later series. He rejected examination with the paraffin technique of sputum, gastric contents, and urine as being of little value—a fact of interest in the light of the recent great strides made with the new Papanicolaou method along those very lines. Zemansky established as criteria for the diagnosis of malignancy the finding of fragments of tissue with definite arrangement of cells to form acini or papillae, or multiple groups of large deep-staining cells. He emphasized as being of importance in the establishment of a final diagnosis, extreme irregularity of cell outline, eccentricity of the nucleus, macronucleosis, the presence of multinucleated cells, and typical or atypical mitotic figures. Most of these criteria have apparently well stood the test of time.

Subsequent investigators have continued to repeat the work done earlier with quite comparable results. Foot brought out particularly the importance of the nucleolar-nuclear ratio as discovered by other investigators, which is often significantly increased in cancer cells. If above 0.30 in his series, he felt that a

Fig 1 Metastatic papillary cystadenocarcinoma of ovary in ascitic fluid a, Smear b, Paraffin section Note that glandular formation is more prominent in the section, but individual cellular characteristics are better demonstrated by one smear $\times 190$

positive diagnosis could be made on that fact alone. He also reiterated the fact that mesothelial cells may cloud the issue considerably. Schlesinger in his article stated that definite positive diagnosis of cancer could be made on paraffin section only on the finding of groups of polygonal cells with polarity, distinct cell walls, and acinar or pseudoacinar formation. He reported that such recognizable microscopic bits of tissue are found in about 60 per cent of malignant effusions. Honigman followed Schlesinger's criteria but added a few cases in his series where cells were found in cords or solid groups with sufficient variation of size, shape, and chromatin content of the nucleus to diagnose malignancy.

With the publication of the monograph on the diagnosis of cancer from the vaginal smear by Papanicolaou and Traut (8) in 1943, vast new horizons opened up in the field of cytology, and in the past few years every conceivable body fluid, almost, has been investigated for malignancy by the application of his technique for collecting various fluids and staining. In 1946 Papanicolaou reviewed his methods (7) and gave a general evaluation of results in all aspects of this work, describing at that time his method of collecting effusions for study.

He recommended that the fluid be mixed with 95 per cent alcohol, half and half, as soon as collected, then centrifuged at moderate speed for 30 minutes. The supernatant fluid is poured off, the sediment smeared on slides, fixed in ether-alcohol, and stained in the same fashion as smears from other sources. The development of the Papanicolaou technique of fixing and staining represents the most important milestone in this work. The immediate fixation of the smear in ether alcohol preserves the sharp cell outline and normal size and permits of more satisfactory staining. By prolonging the time of nuclear staining in hematoxylin and using special cytoplasmic stains in high alcoholic solutions, he secured both sharper nuclear staining and a lighter and more transparent cytoplasmic staining without loss of differential staining of basophilic and acidophilic cells. Nuclear characteristics can thus be defined more accurately and individual cells in thick or bloody smears can be much better differentiated. He noted that searching for malignant cells in a very thin smear is not too desirable because of the relative infrequency of the malignant cell among normal cells in early carcinoma. The widespread use of this technique has further eluci-

dated the cellular criteria of malignancy, so that a positive diagnosis of cancer can be made on study of individual cells with an assurance that was not at all possible before

Hunter and Richardson in 1947 reported a modification of the Papanicolaou technique

which combined both the paraffin block and the Papanicolaou stain Specifically, in the case of transudates and exudates, they advised precipitating the protein from fluid with picric acid, filtration, embedding in paraffin, sectioning, and staining with the new stain The

major advantages that they noted were concentration of cells on the slide, location of all cells in the same focal plane, and the fact that groups of cells were not torn apart with loss of relationship. They recognized the advantage of the stain in securing nuclear detail as well as the fact that its use is free of any technical difficulty.

During our work in vaginal cytology we recently became interested in the study of ascitic and pleural fluids particularly for malignant cells and began to collect cases of effusions which were suspected of being malignant. It should be remarked here that all effusions collected were not routinely examined for cells, but only those in which a suspicion of cancer existed were sent for study. Modifications of technique used in preparing these fluids for examination were as follows: (1) collection of effusion and immediate centrifuging without half and half mixture with alcohol, (2) direct smear of any coagulum in the fluid, (3) refrigeration alone, if immediate examination is not feasible, (4) addition of acetic acid to bloody fluid. These changes were developed when it was noted, first, that the addition of alcohol to effusion when collected invariably produced a thick, flocculent precipitate which could be packed down by centrifuging with difficulty, and often not eminently satisfactorily. Considering the fact that malignant cells are lighter than normal cells, we did make smears from the top surface of the centrifuged material as well as from the lower areas. It was discovered, however, that results were much more satisfactory when no alcohol or other precipitating agent was added to the fluid at all. It has become routine here to collect the specimen and centrifuge immediately. The small sediment that is usually found at the bottom of the tube is smeared on slides. While still wet, the slides are immersed in ether-alcohol, fixed and stained in the usual manner outlined by Papanicolaou. If no sediment appears after centrifuging, most of the fluid is carefully poured off and the small amount in the bottom of the tube is smeared directly. If any coagulum is noted in the fluid before centrifuging, good results are obtained by making a direct smear of that, in addition to following through with the usual routine.

In all cases, comparisons were made between specimens of fluid centrifugated directly and those mixed with alcohol at time of collection. Invariably, the smears made from the alcoholic protein precipitate were less satisfactory than those centrifugated directly, in fact, most often no cells were seen on the former while definite malignant cells were found on the latter. A further advantage of the direct centrifugation is that the smears fix very readily to the slide making unnecessary the use of an albumin base before smearing, while, as is known, the sediment from specimens treated with alcohol will wash off slides too easily during the staining unless smeared on a slide prepared with a layer of albumin. In our cases where no sediment appeared after centrifuging, and this applies to sputum, gastric juice, or any other fluid, and when we found it necessary to smear the fluid directly, it was noted that letting the edges of the smear dry, as advised, before immersing in ether-alcohol, was advantageous in fixation. If a fluid specimen cannot be centrifuged immediately cells can be preserved adequately for a short time by keeping the specimen at refrigerator temperatures. We have examined fluid as much as 4 days after collection and found adequate cellular material, providing it was refrigerated. One other aid in the collection and examination of fluid for cytological study is to add acetic acid to grossly bloody or even blood tinged specimens to lysis the red cells. It is perhaps best to add only enough acid to dissolve partially the red blood cells, in that the presence of a moderate number of those cells as a background is advantageous in reading the slides.

Since this study was initiated fairly recently we have been unable, as yet, to gather a very large series of cases, therefore, in so far as clinical material is concerned, this must be in the nature of a preliminary report. However, even with the relatively small number of cases so far studied, results have been quite conclusive and compare favorably with previously reported percentages by the paraffin block method. Every specimen of fluid that has been examined by the Papanicolaou method has also had simultaneous paraffin blocking, sectioning, and staining with hema-

CHART I

Case	Diagnosis	Fluid	Papanicolaou smear	Paraffin block

M P	Cirrhosis of liver	Ascitic	Negative	Negative
C G	Cirrhosis of liver (biopsy)	Ascitic	Negative	Negative

toxylin and eosin by the pathologist in routine method used in this hospital, thus affording valid comparison of the results of the two different methods both technically and diagnostically. A total of 17 cases of suspected malignant effusions have been received thus far, of these, 5 were pleural and 11 abdominal. Nine positive diagnoses were made, all adenocarcinoma, while 8 negative slides were reported. Although independently arrived at, results have checked in both series, Papanicolaou and paraffin, exactly. However, it should be reported that 2 of the paraffin block sections originally reported negative later were changed to positive on further examination of the smear. On the other hand, one of the Papanicolaou smears reported first as positive later, on consultation, was changed to negative, the cells seen being finally diagnosed as abnormal histiocytes.

Considering the 9 positive cases first (Chart 1) 5 have been confirmed definitely by operation, at which time biopsy or surgical specimen returned the positive diagnosis. The other 4 cases, while not having been operated upon or subjected to postmortem examination, all had very positive clinical evidence of malignancy. A breakdown of the 8 negative cases reveals the following clinical or pathological diagnoses. There were 3 cases of pleural effusion on the basis of tuberculosis or of undetermined etiology. One lymphosarcoma diagnosed by lymph node and liver biopsy failed to show malignant cells in the ascitic fluid, though lymphocytes of relatively normal appearance were present. One case of retroperitoneal sarcoma diagnosed at exploratory laparotomy failed to show cancer cells in ascitic fluid examined from several subsequent paracenteses. One adenocarcinoma of the stomach was negative on fluid examination, and finally 2 cases of cirrhosis of the liver showed negative smears and paraffin sections. It is interesting to note that the mesothelial cells mentioned by earlier observers were seen in the Papanicolaou smears of one of the latter cases and were not as obvious in the paraffin section.

In comparing slides of the two series (see photographs) it has been found that either method adequately demonstrates malignant cells, with individual case variation. Some of the paraffin slides are superior in demonstration of tissue groups, though their counterpart smeared slides show a large number of unquestionably malignant cells. Often groups of cells in acinar or papillary formation do appear on the smeared slides by the technique outlined above, as well as on the paraffin sections. In one or two cases where the sediment was less abundant, more malignant cells were actually seen on the smears than in the paraffin section. In diagnosing carcinoma from paraffin block, our pathologist has limited himself to accepted criteria of groups of malignant cells in acinar or papillary formation. We have found in our own series that the careful application of the cellular criteria of malignancy is satisfactory for making the diagnosis on individual cells, though the presence of characteristic groups is to be desired. Those

criteria used have been hyperchromatism, with clumping of granules in irregular aggregations or dispersion to the periphery, definite enlargement of the nucleolus or the presence of multiple nucleoli, thickening of the nuclear membrane, relatively large nuclearcytoplasmic ratio, and alternation in the shape of nuclei with fragmentation producing multinucleated cells (6). A change in the amount and shape of the cytoplasm has also been considered. The statement of Papanicolaou that "anisocytosis associated with anisonucleosis constitutes an important diagnostic point because it rarely occurs in nonmalignant conditions" has been borne out. It has been a combination of many of the above criteria rather than the presence, however marked, of any individual standard that has guided the diagnosis of malignancy in the single cell. Particular stumbling blocks have been histiocytes and mesothelial cells, and these must be always considered in all smears. Although the great majority of fluids were examined with no more information than the name of the patient, ward, and origin of the fluid, it is felt that an adequate case history should accompany all specimens, not to influence the examiner unduly but to aid in interpretation of doubtful smears.

We feel that both methods of fluid examination have certain advantages as presented in the following:

Papanicolaou method

- 1 Better nuclear staining. Nuclear structure is much better defined enabling one to make a diagnosis more readily where acinar formation does not appear.

- 2 Less cellular shrinkage. Smears prepared by the Papanicolaou method show cells significantly larger than the cells in the paraffin slide. This is probably due both to the fact that cells in the paraffin section are somewhat shrunken by fixation and that sectioning tends to cut a majority of cells in a plane which does not go through one maximum diameter of the cell. It is often possible to pick up malignant cells with simple low power screening in the former, without the aid of acinar formation.

- 4 Possibility of greater percentage of positive diagnoses. Although this series is very small and has not as yet found a positive

case which was not eventually diagnosed by the paraffin method as well, it is believed that where minimal exfoliation into malignant effusion has occurred, a smear is more apt to demonstrate malignancy. Furthermore, there are 2 cases in this series where sediment was insufficient for paraffin blocking, and smearing and staining were done by the pathologist with hematoxylin and eosin. This smear was less satisfactory than the Papanicolaou slide.

Paraffin block

- 1 More frequent appearance of acinar or papillae. In positive cases the paraffin section is more likely to show typical malignant gland formation than the smear method.

- 2 Concentrated cellular material. On the paraffin section cells are concentrated in a small area, making examination of the slides somewhat more rapid.

- 3 Cells in same focal plane. On sectioning, all cells lie in one plane, while a poorly made smear may necessitate frequent change of focal plane in examination.

- 4 Technique well established. The paraffin method has been in use in most hospitals for many years and there are trained technicians, as well as pathologists, well versed in the method.

In general, both methods of examination of transudates and exudates have been found to compare very closely. Each has certain advantages and disadvantages, though the end result remains the same. Because of the widespread use of paraffin blocking, it is believed that this method will remain the standard one for fluid examination, especially in view of the present lack of many properly qualified cytologists. However, it is also felt that the more widespread use of the Papanicolaou smear technique may result in a higher percentage of positive diagnoses, and represents a definite advance. Perhaps the ideal condition would be the maintenance of both methods of examination on all effusions, both as a double check and to increase the incidence of diagnosis. If a situation exists in which the paraffin method is not available, then it is our belief that the alternative method is equally adequate for purposes of diagnosis at least.

SUMMARY

1 A brief review of the history of the diagnosis of cancer in transudates and exudates has been presented

2 A small series of cases has been reported comparing Papanicolaou's method of examination of smears and the older established paraffin blocking and sectioning

3 In examining smears of fluid, the following modifications of method were used with more satisfactory results (a) collection of effusion and immediate centrifuging without half and half mixture with alcohol, (b) direct smear of any coagulum in the fluid, (c) refrigeration alone, if immediate examination is not feasible, (d) addition of acetic acid to bloody fluid

4 Of 17 cases reported, 9 gave positive diagnoses while 8 were negative, or 53 per cent uncorrected positive cases. Of the negative fluids reported, 3 cases had proved malignancy, while 2 cases were definite cirrhosis of the liver (liver biopsy). Three pleural effusions have not had etiology definitely estab-

lished. For a total of 12 proved cases of malignancy then, 9 had malignant effusion demonstrated by microscopic examination of fluid, or 75 per cent

5 The relative advantages and disadvantages of both methods have been listed with the conclusion that either method is valid, that a combination of both or wider use of the Papanicolaou technique may increase the percentage of positive diagnoses of malignancy in effusion

THE BONE BANK

A DEPARTMENT of spare parts seems destined eventually to be part and parcel of every modern hospital, just as such a department is today an integral part of every modern garage. In most instances, human tissues seem to be best preserved for future use by refrigeration, and bone is no exception. There is some evidence to support the belief that it may not be necessary to preserve the organic elements of bone in a viable state.

Syngene-sioplasmic, homogenous and heterogenous bone transplants in various forms have been employed successfully but sporadically for a number of years. Only recently Reynolds and Oliver, in an exhibit at the meeting of the American Academy of Orthopedic Surgeons, demonstrated the use of homogenous bone transplants preserved in a weak aqueous solution of merthiolate in a manner similar to that used for a number of years to preserve transplants of cartilage.

Walsh¹ pointed out that it was the opinion of Dr. A. E. Osterberg that bone treated with a 1:1,000 aqueous solution of merthiolate would maintain sterility but that the antiseptic agent also would affect adversely the protein matrix of the bone. Likewise, homogenous bone preserved in alcohol and other antiseptic solutions or fresh or dried bone sterilized by boiling or autoclaving has been used. Bone thus preserved or sterilized can serve only as a supply of inorganic calcium and phosphorus and as a trellis or framework for the process of "creeping substitution" as described by Phemister.² The protein matrix would be adversely affected by such treatment, with the possible result that a foreign body reaction would be induced in the host.

Walsh, in summarizing his thesis concerning the preservation of bone, made the following statements:

"In preserving tissues for transplantation at a later date, three principles must be observed:

"1 The cells of the tissues should be kept viable

"2 If viability is not possible or necessary, the tissue must be preserved from degenerative changes

"3 The tissue must be maintained in the same aseptic state as it was when placed in the preserving containers

"From a study of the literature it would appear that all these principles can best be fulfilled by preservation at a temperature below -20°C. Above this degenerative changes

¹ Walsh, A. C. I. The use of homogenous and heterogenous bone in bone grafting. II. A method of preserving homogenous bone for use in bone grafting. Thesis, Graduate School, University of Minnesota, 1947, 79 pp.

² Phemister, D. B. *Ann. Surg.*, 1935, 102: 261-285.

occur and sterility cannot be assured. Temperatures below -25°C appear to be of no practical value."

All the experimental evidence thus far points to the fact that probably none of the bone cells of refrigerated bone transplants remain viable after being transplanted into the host. However, most observers feel that even in the case of fresh autogenous bone transplants, only a few, at most, of the peripheral cells remain viable. Certainly, the chief value of any bone transplant other than the support and fixation which it might offer seems to be in the framework and mineral salts which are supplied.

Osteogenesis proceeds to the same end, whether autogenous or frozen homogenous transplants are used, provided there is a "take" of the transplant. It is the opinion of Bush¹ and others who have done investigation along this line that this end is reached sooner in the case of autogenous transplants than in the case of homogenous transplants. In other words, if we may be permitted a practical simile, in going from Chicago to New York the former proceeds by a direct route and the latter by Washington, D C. For this reason, I doubt that the autogenous bone graft will ever be completely replaced by the homogenous transplant. We do not have evidence as yet in a large series of comparable cases that the percentage of "takes" of frozen homogenous transplants is as high as that of fresh autogenous bone, and I doubt that such will be the case. Therefore, at this stage frozen bone should not be used routinely, and certainly each case in which it is proposed to use it must be carefully evaluated. Possibly it will be demonstrated that frozen homogenous bone will have its greatest efficacy when it is mixed with fresh autogenous transplants.

The source of bone for the bone bank is almost limitless, provided the bone to be stored is removed under aseptic conditions. Upon removal of the graft from the donor, the bone is placed in a sterile container with a seal cap, and this container is placed in a second sterile container or wrapped in sterile surgical linen. It is then immediately placed in a deep-freeze unit which maintains a constant temperature of -20°C to -25°C . The bone is then left in the freezer until a few minutes before the time when it is to be used.

Walsh, in experimental work, has shown that under such conditions bone apparently will remain sterile and viable for an indefinite period, although we hesitate at the present to use bone if it is more than three months old. At present, most of the bone bank supply which is used by my associates and me is obtained by freezing segments of ribs removed during the course of combined thoracolumbar sympathectomy, and other thoracic operations. Formerly, these segments of ribs were discarded. Traumatic amputations and fresh cadavers conceivably could furnish unlimited supplies of suitable bone for the bank, provided permission could be obtained from the patient or the relatives for its use.

It has been shown by Ghormley² and others that the blood group of the donor does not have to be compatible with that of the recipient as far as the use of homogenous bone transplants is concerned. The history of the donor must be free of any record of syphilis, and serologic tests must rule out this disease, for it has been shown that the *Treponema pallidum* may survive at a very low temperature. Likewise, the donor should not have had jaundice. Nor do we feel it advisable to use bone from any

¹ Bush, L. F. J. Bone Surg. 1947, 29: 620-628

² Ghormley, R. K. Ann. Surg., 1942, 115: 427-434

donor in whom there may be question as to the presence of an infectious or a malignant neoplastic illness. The aforementioned factors together with the age, sex, nationality, occupation, past and present illnesses of the donor and recipient, should be set down and filed for future reference.

By the use of homogenous bone grafts the patient is spared the shock, increased morbidity, and cost of a second operative procedure. We have found the bank of especial use in the surgical treatment of children, where the supply of autogenous bone is scant and for filling in large cystic lesions and giant cell tumors and for the reinforcement of autogenous grafts. It is possible that a combination of autogenous and homogenous transplants will prove more efficient than the use of the latter alone, although experimental work along this line has not yet been performed.

At this stage of our knowledge it is felt by most surgeons using bone transplants that the autogenous graft is the one of choice in most instances, provided the operative risk and postoperative morbidity will not be seriously affected by the removal of such a graft at the time of definitive surgical treatment, and provided a sufficient supply of autogenous bone can be obtained. In those instances already mentioned in which the factors in question do not apply, the surgeon would be justified in using frozen homogenous transplants or a combination of autogenous and homogenous transplants. Not until large, comparable series of the use of the two types of transplants have been critically compared will the average surgeon be justified in the routine use of homogenous grafts, whether they are preserved by refrigeration, by aqueous solution of merthiolate, or by other antiseptic means.

PAUL R. LIPSCOMB

CONGENITAL DEFORMITIES OF THE FEET

CONGENITAL deformities of the feet are produced by the same factors which produce deformities in other parts of the body. Mall divided them into primary and secondary deformities. Primary deformities result from some inherent defect of the fertilized ovum. Murphy said that primary congenital malformations arise solely from influences which affect the germ cells prior to fertilization.

In secondary congenital deformities, it is assumed that the fetus is at first normally formed, but that later deformity is produced by the action of some extraneous cause. Piette suggested that deformities and monsters may be due to fertilization of a dying ovum or a dying spermatozoon. Hobbs showed that injury to gonads of animals by roentgen rays will cause inheritable deformities. Workany and Schraffenberger produced congenital malformations in the offspring of female rats by exposing them to roentgen rays. Beveridge H. Moore found that children of parents with neurofibromatosis were more apt to develop deformities. Gregg in 1941 and later Swan and others have reported many cases to prove that if the mother develops rubella during the first three months of pregnancy the child is apt to have congenital cataract, heart disease, deafmutism, microcephaly and glomerular sclerosis.

Warkany and Nelson and others report deformities in rats when the mother is placed on a deficient diet. These can all be prevented by adding two per cent pig liver to the diet. They found that of all vitamin B derivatives, riboflavin was the only one which would prevent deformities. This was effective if given only between the 12th and 14th days when the limb buds of the rat were developing.

Bohm showed in 1929 by serial sections of early human embryos that as the limb bud develops, the foot is in a clubfoot position and that congenital clubfoot is due to an arrest of development. As further development occurs in most cases, the foot turns into the normal position. We assume that there is some unknown stimulus which causes the foot to progress to a normal foot. If the lack of riboflavin in rats allows deformities to occur, might not the lack of riboflavin or some unknown stimulus in human beings allow the foot to remain in the clubfoot position?

Nine congenital deformities may occur in the feet. Some of these are so evident they offer no problem in diagnosis. *Congenital absence of parts* may vary from the absence of a part of a toe to the absence of the entire foot. *Congenital hypertrophy* may involve one or more toes or the entire extremity. In *polydactylism*, the physician may perform an inadequate operation by simply removing the extra toe, thus leaving the enlarged part of the metatarsal or the extra metatarsal. A roentgenogram should be made and a complete operation done. Syndactylism in most cases is no handicap. When the ends of the toes are held together by a small adhesion this should be divided.

The deformities following *spina bifida* and *arthrogryposis multiplex congenita* often differ considerably from those of typical clubfeet or flat feet, but the treatment is essentially the same. The club foot following *spina bifida* is usually more easily corrected than the average congenital clubfoot. The deformities associated with arthrogryposis are much more difficult to correct and are more prone to recur. *Congenital calcaneovalgus* may be only a mild flat foot or may be a reverse clubfoot and very rigid and difficult to correct.

The most common congenital deformity of the foot is *congenital clubfoot*, or talipes

equinovarus. One out of every eleven children brought to the Scottish Rite Hospital has clubfeet, 1 of 5 has some congenital deformity.

The earlier congenital deformities are corrected, the easier they are to correct and the better the chance for the correction to be retained. This is especially true for clubfeet. The correction should be accomplished by a method which will do no harm to the foot. Years ago attempts were made to correct the deformity in one operation by crushing the foot in a special machine or by wrenches. This procedure improved the appearance of the foot, but left it stiff and rigid. When the deformity recurred, further corrections were still more difficult.

Later it was found that clubfoot deformity could be corrected gradually by a series of casts and wedgings. This took much more time but gave a flexible foot and one very closely resembling a normal foot in appearance and in function. The plaster method, however, is a laborious method, and requires a very exacting plaster technique, the foot must be untwisted in a very definite manner. The beginner has difficulty in applying casts to struggling babies, and difficulty in keeping the casts on. Sores often occur under the casts and still more frequently he fails to correct the deformity. If he carries his correction too far, a flatfoot may result, and if not carried far enough, the clubfoot will recur. Clubfeet tend to relapse to the position at birth.

Because of the difficulties accompanying the plaster treatment, many modifications of metal splints have been made. The position of the foot cannot be as accurately controlled by splints. The feet are often turned over too far into a flatfoot position. For this reason there may be fewer recurrences after treatment with splints. The test of any method is not how few recurrences a method gives, but how near to normal the foot is after treatment.

The second most frequent congenital deformity of the foot is *congenital metatarsus varus*, which is a third of a clubfoot. Twenty-five years ago this was not recognized as a separate and distinct entity but was thought to be a mild form of clubfoot. A clubfoot presents three deformities: forefoot adduction, inversion of the foot and equinus deformity. Metatarsus varus or metatarsus adductus presents chiefly forefoot adduction. There is an inversion of the forefoot. The heel is sometimes in valgus, sometimes in varus, but not always in varus as in a clubfoot. These feet never show any equinus deformity, but can always be brought in full dorsiflexion. This one sign separates them from clubfeet.

In times past when the newborn was examined, and it was found that the feet were not clubbed, it was assumed that they were normal. This is no longer true. In metatarsus varus the deformity may be so mild at first, it is overlooked on a casual examination. The muscles are out of balance just as they are in a foot following poliomyelitis. No deformity is present immediately after the attack of poliomyelitis and we do not look for a deformity to make the diagnosis. In metatarsus varus the slight deformity present at birth is made worse by muscle imbalance. The anterior tibial constantly pulls the foot in and up in a clubfoot position. As time goes on this deformity becomes more noticeable. There is a structural change in the foot that is easily discernible. A prominence is seen and felt on the lateral border of the foot near the base of the fourth and fifth metatarsals and the cuboid. The arch is higher than normal. When the posterior part of the foot is held in the hand, the forefoot cannot be abducted to the midline. A much wider variation in the severity of the deformity is present in metatarsal varus feet than in congenital clubfeet.

The treatment of metatarsus varus feet con-

sists of stretching the forefeet in abduction in the very mild cases and the wearing of "swungout" shoes. Most of the patients will need a series of casts and wedgings just as is used for clubfeet. The feet should not be strapped in abduction with adhesive as this will increase the valgus deformity of the heel. Metal splints should not be used for the same reason. In using casts, care should be taken not to overcorrect these feet into a flatfoot position. It is less embarrassing to the surgeon to correct a recurrence produced by nature than it is to correct a flatfoot he has produced.

Congenital metatarsus varus is very definitely on the increase. From 1925 to 1940, the writer saw less than a dozen such cases. During the last eight years the number has increased to nearly three hundred. Most of these have been seen in the last three years.

There must be some reason for this recent increase in metatarsus varus cases. As stated above, riboflavin can prevent deformities in rats. We do not know that human beings and rats behave alike in this respect, neither do we know that the diet of the mother is deficient in vitamin B. This we do know for the last few years obstetricians have been giving mothers multiple vitamins as soon as they come under observation. To prevent foot deformity these should be given during the fifth and sixth weeks when the limb buds are forming. Most mothers do not begin taking vitamins until the second or third month. Vitamins then do not prevent the deformity but furnish the stimulant for the foot which was predestined to be a clubfoot to develop into a more nearly normal foot, so at birth the child has only a "third of a clubfoot." May not the taking of multiple vitamins account for the increase in the number of metatarsus varus deformities, and the time at which they are begun account for the wide variation in the degree of this deformity?

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE biography of Oliver Wendell Holmes by Eleanor Tilton¹ is a well written and factual narrative which describes the life and environment of Holmes in an entertaining manner. The book is definitely not a medical biography and the medical life and contributions of Holmes receive less emphasis than his poems, epigrams, speeches, and novels. He is depicted as one of the most versatile men of American medicine, being a physician, poet, author, and philosopher of note. The description of his education in the basic sciences and medicine more than 100 years ago should be of especial interest to physicians today. His critical opinions of many of the medical giants of France under whom he studied, such as Louis, Marjolin, Roux, Velpeau, Ricord, and Lisfranc are noteworthy. Other medical topics of interest include the introduction of anesthesia and his investigation of the contagion of puerperal sepsis. Throughout his life, his diminutive size and frailness were more than compensated for by his many intellectual gifts and developments. His reactionary nature to his early home life and education are reflected later in his severe study of medical science, his development of a skeptical attitude toward established modes of treatment, his admiration for sincerity and truth, and his realization of the accumulative value of personal experiences in clinical medicine.

W A ALTEMEIER

THE book, *The Parathyroid Glands and Metabolic Bone Disease, Selected Studies*,² by Fuller Albright and Edward C Reifenstein, Jr., is an important and invaluable contribution to a complex subject.

Dr Fuller Albright is justly regarded as the outstanding authority in this country on clinical metabolic investigations in general and the study of the interrelationships linking calcium metabolism, the parathyroid glands, and bone in particular. This status is a natural outgrowth of the remarkable and unique series of shrewd clinical observations, careful and painstaking metabolic balance studies, and brilliant and open minded theorizing which Dr Albright, Dr Reifenstein, and other colleagues have contributed during the past 2 decades. The present extraordinary volume comprises an integrated and

detailed summary of some of these contributions, in some cases altered and brought up to date. No attempt is made to present any systematic or comprehensive monograph on the subjects discussed.

The subjects covered include chapters on the normal and pathologic physiology of the parathyroid glands, clinical hyperparathyroidism and hypoparathyroidism, vitamin D and dihydrotachysterol, osteoporosis, osteomalacia, polyostotic fibrous dysplasia, and Paget's disease. Included among the subjects covered in some detail under these headings are senile and postmenopausal osteoporosis, the osseous lesions of Cushing's syndrome and Grave's disease, Milkman's syndrome, and the various renal osteodystrophies (renal rickets, Fanconi's syndrome, and "tubular insufficiency without glomerular insufficiency").

A remarkable quantity of original observation has been compressed into this book. However, the authors are not at all content merely to present data; they try, wherever possible, to develop a hypothesis on which to hang the observations. In Albright's hands, a hypothesis becomes a research tool in itself, to be welded with skill so long as it remains useful. It is quite evident from the comment that the authors, perhaps better than the reader, appreciate the shortcomings and limitations of the theories presented. In a characteristically candid "prophylactic criticism" which they include in the preface, the authors state "The hypotheses—it almost follows—are subject to change without notice."

If for no other reason than that it is a convenient source book for the large quantity of experimental data which are reported in detail, the book would be invaluable to serious students of the field. However, the authors' extensive clinical experience with the conditions mentioned will make it, in addition, an authoritative and indispensable text for internists interested in metabolic and endocrine disturbances, as well as for urologists, orthopedists, and general surgeons.

The volume is superbly written in a clear and informal style, and the subject matter is arranged in a sensible and well organized manner. The numerous illustrations are of good quality. A complete bibliography and excellent subject index are included. In addition, the text is carefully annotated with numerous cross references which should expedite its use as a reference work. An appendix provides details of methods of analysis and study, including methods for calculating and plotting metabolic balances. The book is well printed and bound, and contains com-

²THE PARATHYROID GLANDS AND METABOLIC BONE DISEASE, SELECTED STUDIES. By Fuller Albright, A.B. M.D. and Edward C. Reifenstein, Jr. A.B. M.D. F.A.C.P. Baltimore: The Williams & Wilkins Co., 1948.

paratively few typographic errors. It is hard for this reviewer to see how either authors or publishers could have done a better job. F. R. KEATING, JR.

THE small volume entitled *Clinical Endocrinology for Practitioners and Students*,¹ is a well organized primer which deals with the anatomy, physiology, and clinical characteristics of the endocrine glands. Its simplicity and correctness are particularly com-

mendable in view of the myriad sources among clinicians, biochemists, physiologists, and all round enthusiasts from which material for such a text would be derived. Its qualifications for the practitioner and the medical student are excellent since each chapter contains not only the fundamental concepts pertaining to each gland but specific directions concerning the treatment of dysfunctions. It is only to be regretted that the bibliography, necessarily brief, includes references to secondary investigators and journals and fails to stress many key papers of permanent historical interest. The impression thus conveyed is that the book was compiled more from reviews than from the original sources.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

DALLAS B. PHLMISTER, Chicago, *President*
FREDERICK A. COLLIER, Ann Arbor, *President Elect*

PRELIMINARY PROGRAM FOR THE 35th CLINICAL CONGRESS—THE STEVENS, CHICAGO

OCTOBER 17 TO 21, 1949

CHICAGO, which during the week of October 17 to 21, 1949, will entertain the Clinical Congress of the American College of Surgeons for the ninth time has played a significant part in the development of the organization and has many attractions to offer the visiting surgeons and hospital representatives. It was host city to the first Clinical Congress of Surgeons of North America in 1910, three years later, it was the setting for the First Convocation of the American College of Surgeons, which met in conjunction with the Clinical Congress in that year of its founding, 1913, and annually thereafter until 1917 when the Clinical Congress was merged with the College. Centrally located, and with excellent medical center prospects, it was selected as the headquarters of the College, and in 1919 surgeons of the city and their friends presented it with the magnificent building which it occupies at 40 East Erie Street, to which was added in 1926 the John B. Murphy Memorial Auditorium which is now connected to it on the East.

The medical center prospects of Chicago as they appeared early in the century have been realized beyond the expectations of the most visionary of the prophets, and the atmosphere is one of much greater things to come. The city even now actually has three great medical centers—on the south side, centering around the University of Chicago, on the west side, centering around the University of Illinois professional schools and hospitals, Cook County Hospital, Presbyterian Hospital, Chicago Medical College, and other institutions, and on the near north side, centering around Northwestern University, Wesley Memorial Hospital, and Passavant Memorial Hospital, with Mercy Hospital about to build

nearby, which will bring in the Loyola University influence. No other city in the world has five accredited medical schools.

Chicago has 68 hospitals which are approved by the American College of Surgeons, 23 of which are also approved for graduate training in surgery and the surgical specialties.

Chicago is the headquarters city for many medical and related organizations besides the College, such as the American Medical Association, the American Hospital Association, the American College of Hospital Administrators, and the American Dental Association.

The medical and hospital resources of the city will be heavily drawn upon to make the thirty-fifth Clinical Congress, and the Sixth Inter-American Congress of Surgery which will meet with it and continue for two days longer, educational events of the highest character. In addition, the speakers and discussion leaders will include outstanding authorities from overseas and from Latin-America, as well as from the United States and Canada.

Advance registration figures indicate that the thirty-fifth Clinical Congress may be the largest of all the Congresses to date.

SIXTH INTER-AMERICAN CONGRESS OF SURGERY

The Sixth Inter-American Congress of Surgery will meet as a part of the Clinical Congress on Monday through Friday, will have its Inaugural Session on Friday morning and will continue with scientific, business and social sessions on Saturday and Sunday, October 22 and 23. An outline of the program appears in a succeeding article.

Many delegates and other surgeons from Latin American countries are registering, along with

AMERICAN COLLEGE OF SURGEONS

their colleagues from the United States and Canada, in anticipation of a seven-day surgical program of extremely great interest.

Every Fellow of the American College of Surgeons is a member of the Association of Inter-American Congresses of Surgery by virtue of the fact that the College is a signatory member of that organization. Its scientific and social sessions on Saturday and Sunday are therefore open to all Fellows. The members of the other signatory societies of the Association are likewise entitled to attend the Clinical Congress clinics and scientific meetings, since it is the practice for the host country to make a joint event of its own annual surgical Congress and that of the Inter-American group.

COLOR TELEVISION

Telecasts in color of operations taking place at St. Luke's Hospital will be shown in the Normandy Lounge of The Stevens every afternoon, Monday through Thursday, and every morning except Monday. Dr. Foster L. McMillan of the hospital staff is television chairman. Dr. Kendall A. Elsom of Philadelphia, Assistant Professor of Clinical Medicine, Medical School of the University of Pennsylvania, who directed the television program at the American Medical Association convention in Atlantic City in June, will be the co-ordinator.

This demonstration is made possible by Smith, Kline & French Laboratories of Philadelphia. It was at their request that Columbia Broadcasting System, Inc., undertook to specially design and manufacture color television equipment, the first of its kind to date, is owned by the Laboratories and is being demonstrated by them throughout the country as a contribution to medical teaching. The showing at the Clinical Congress will be only the third demonstration of color television in surgery, the first having been at Atlantic City in June and the second at the meeting of the Colorado State Medical Society in September.

The American College of Surgeons was the first organization to use television in the scientific program of a large meeting. In September, 1947, during the thirty-third Clinical Congress, a series of operations was televised from The New York Hospital to a conference room at the Waldorf-Astoria. Television was employed for the second time at a Clinical Congress in October, 1948, when operations were televised from the Los Angeles County Hospital to the Philharmonic Auditorium and to a room at the Los Angeles Biltmore Hotel. Both of these demonstrations were in black and white. The New York showing

was made possible by a grant from the Johnson & Johnson Research Foundation and the Los Angeles showing was sponsored by the *Los Angeles Times*. The tentative color television program appears in a succeeding section.

ADDITIONAL TELEVISION

Under a grant from Ciba Pharmaceutical Products, Inc., Lewis Memorial Maternity Hospital is scheduling a program of obstetrical procedures under saddle block anesthesia, and other obstetrical and gynecological operations, which will be televised, in black and white, within the hospital. The Radio Corporation of America is handling the installation. About twelve screens will be used, some of which will be large, and an estimated total audience of 500 can be accommodated. The clinics are scheduled from 9:00 to 11:30 each morning and from 1:00 to 3:30 each afternoon. The preliminary program appears under the hospital name with the other hospital clinics on succeeding pages.

CLINICS

Operative and non-operative clinics will be held on Tuesday through Friday mornings, and on Monday through Friday afternoons, in 23 hospitals, all of which are approved by the American College of Surgeons for graduate training in surgery. Twenty-two of these are within city limits, and one, Evanston Memorial Hospital, in Evanston. A preliminary outline of the clinical program appears in a succeeding section. The program will be finally revised and amplified immediately preceding and during the Congress, and published in a *Clinical Bulletin* which will be distributed each day at the headquarters hotel, The Stevens. Tickets for the clinics will be placed on open distribution at the Clinic Ticket Desk in the Exposition Hall without advance requisition. Tickets for Monday clinics may be obtained on Sunday afternoon, October 16, from 3:00 to 6:00 p.m. Tickets for Tuesday through Friday clinics will be available beginning at 8:00 a.m. on the day before the clinic is scheduled.

PRESIDENTIAL MEETING

The Presidential Meeting will be held on Monday evening, October 17. The complete program appears on another page. At this meeting the officers-elect, consisting of Dr. Frederick A. Coller, of Ann Arbor, president, Dr. Donald G. Tollefson, of Los Angeles, first vice-president, and Dr. Robert M. Moore, of Galveston, second vice-president, will be installed. The outgoing president, Dr. Dallas B. Phemister, of Chicago, will

preside and will deliver the Presidential Address. His subject will be, "An Evaluation of Full-time and Group Practice for the Clinical Faculty of a Medical School."

Sir James Learmonth, of Edinburgh, will deliver the fourth Martin Memorial Lecture. His subject will be "Collateral Circulation, Natural and Artificial."

CONVOCATION

The formal initiation ceremonies for the new Fellows will be a colorful feature of the annual Convocation which will be held on the final evening, Friday, October 21. Honorary Fellowships will also be conferred on this occasion. Lord Webb-Johnson, of London, president of the Royal College of Surgeons of England, will deliver the Fellowship Address. His subject will be "Science in Surgery—Stop, and Look, and Listen."

It is interesting to note that the dedicatory address at the first Convocation of the American College of Surgeons, held in the Gold Room of the Congress Hotel in Chicago on the evening of November 13, 1913, was presented by Sir Rickman Godlee, then President of the Royal College of Surgeons of England, which sent greetings through him in the form of an illuminated parchment.

GENERAL SURGERY

In general surgery, the program at the headquarters hotel will embrace three evening symposia and six afternoon panel discussions.

The subjects for the symposia on Tuesday, Wednesday, and Thursday evenings, respectively, will be "Acute Surgical Emergencies in Gynecology and Obstetrics", "Blood Coagulation and the Use of Anticoagulants", and "Malignant Disease." At the Wednesday evening session there will also be presented the Fracture Oration by Dr Otto J. Hermann, of Boston, on the subject "Fracture Hazards."

The following subjects have been chosen for the afternoon panel discussions in general surgery, the first one of which will be held from 1:30 to 3:00 and the second from 3:30 to 5:00 o'clock on Monday, Tuesday, and Wednesday: "Surgical Lesions of the Breast", "Fractures of the Skull", "Massive Upper Abdominal Hemorrhage", "New Surgical Technics in Drug Treated Infections", "The Management of Acute Emergencies Occurring during Operations", and "Preoperative and Postoperative Care and Anesthesia for Infants."

Detailed programs are published on succeeding pages.

SURGICAL SPECIALTIES

Panel discussions on the surgical specialties will be held on Friday afternoon from 1:30 to 4:45

o'clock. The panels will be held concurrently in the following fields: orthopedic surgery, plastic surgery, urology, thoracic surgery, neurological surgery, and obstetrics and gynecology. Programs are shown on succeeding pages.

OPHTHALMOLOGY AND OTOLARYNGOLOGY

Separate programs are planned for Ophthalmologists and Otolaryngologists on Tuesday, Wednesday and Thursday of the Congress week. Since the annual meetings of the Academy of Ophthalmology and the Academy of Otolaryngology will be held in Chicago during the week immediately preceding the Clinical Congress, the Congress programs for these two specialties are being modified to suit this unusual sequence.

During the forenoon and afternoon the programs for these two specialties will consist of operative clinics and demonstration clinics which will be held in several Chicago hospitals and in medical motion picture programs for these two specialties at the Clinical Congress headquarters in the Stevens Hotel.

Evening sessions at the Congress headquarters in the Stevens Hotel, according to preliminary plans, will be as follows:

Tuesday 8:00 p.m.

Recent Developments in the Field of Allergy as Related to Otolaryngology. GOSTA DOHLMAN, M.D., Professor of Otolaryngology, Lund University, Lund, Sweden.

Thursday 8:00 p.m.

The Dependence of Surgery on Physiology as Exemplified in the Treatment of Glaucoma. SIR STEWART DUKE ELDER, K.C.V.O., F.R.C.S. (Eng.), Director of Research, the Institute of Ophthalmology, University of London, London, England.

SYMPOSIA ON AMPUTEES AND ON TRAUMA

A symposium on "The Care and Education of Amputees" will be held on Tuesday morning from 10:00 a.m. until noon.

On Tuesday afternoon from 2:00 until 5:00 o'clock, a symposium on trauma will be held at which Dr. Robert H. Kennedy of New York, chairman of the Committee on Trauma, will preside.

The programs for these two symposia appear on succeeding pages.

SYMPOSIUM ON CANCER

A symposium on cancer will be held on Wednesday afternoon from 2:00 until 5:00 o'clock, with Dr. Grantley W. Taylor, of Boston, chairman of the Cancer Committee, presiding. The program appears on a succeeding page.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems, one of the most popular features of Clinical Congresses during the past few years, will be held on Monday through Thursday afternoons, and Tuesday through Friday mornings. Two concurrent sessions will be held on Wednesday morning only. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented under the general direction of Dr. Owen H. Wangensteen, chairman of the committee. Forum on Fundamental Surgical Problems. An outline of the main topics follows:

- Monday, 2:00—5:00 p.m.—Gall Bladder and Pancreas, Urology, Orthopedics, Plastic Surgery
- Tuesday, 9:00—12:00 a.m.—Surgery of the Heart
- Tuesday, 2:00—5:00 p.m.—Vascular Surgery and Surgery of Hypertension
- Wednesday, 9:00—12:00 a.m.—Neurosurgery
- Wednesday, 9:00—12:00 a.m.—Thyroid, Lungs, Esophagus, Anesthesia
- Wednesday, 2:00—5:00 p.m.—Stomach and Intestines
- Thursday, 9:00—12:00 a.m.—Wounds and Wound Healing, Burns, Infections, Shock
- Friday, 9:00—12:00 a.m.—Blood and Body Fluids, Portacaval Anastomosis, Cancer

The Thursday afternoon session, from 1:00 to 3:30, will be conducted as a seminar, with Dr. I. S. Ravdin as moderator, on the subject "Nutritional Problems including a Consideration of the Use of Fluids and Electrolytes." Programs appear on succeeding pages.

SYMPOSIUM ON GRADUATE TRAINING IN SURGERY AND THE SURGICAL SPECIALTIES

The Symposium on Graduate Training in Surgery will be held Thursday 10:00 a.m. to 12:30 p.m. with Dr. Frederick A. Collier, Chairman of the Graduate Training Committee presiding. The program will be devoted to subjects of timely interest to all who are engaged in graduate training in surgery.

HOSPITAL CONFERENCES

The twenty-eighth Hospital Standardization Conference will be held during the Clinical Congress. Its opening meeting will constitute the first formal session of the Clinical Congress and will be for both surgeons and hospital representatives. Dr. Dallas B. Phemister, president of the College, will preside.

Hospital administrators, trustees, members of medical staffs, nurses, technicians, dietitians, and heads of the various hospital departments and their personnel, are invited to participate in the discussions at the hospital conferences which will be directed by leading authorities in the hospital field in the United States and Canada. The program will include formal sessions, panel discussions, round table conferences, symposia, and forums. An outline of the program appears on succeeding pages.

ASSEMBLY OF INITIATES

The 1949 initiates will attend an assembly on Friday afternoon from 1:30 to 2:15 o'clock. Dr. Frederick A. Collier, newly installed president of the College, will preside. Dr. Arthur W. Allen, vice chairman of the Board of Regents, and Dr. Bowman C. Crowell, Dr. Malcolm T. MacEachern, and Dr. H. Prather Saunders, associate directors, will briefly outline the program of the College.

OTHER OFFICIAL MEETINGS

A special meeting of the Board of Governors will be held on Sunday afternoon, October 16. The annual meeting of the Governors and Fellows of the College will be held on Thursday afternoon at 3:30 o'clock. Reports on activities of the American College of Surgeons, of great interest to all of its Fellows, will be presented by officers, chairmen, and administrative staff members following the election of officers.

Important committee meetings will be held on Wednesday as follows: State and Provincial Executive Committees, State and Provincial Credentials Committees, and Committees on Applicants and Judiciary Committees, 10:00 a.m. to 12:00 Noon, the Committee on Trauma and Regional Committees (formerly the Committee on Fractures and Other Traumas), 3:30 to 5:30 p.m., and the annual dinner and meeting of the Cancer Committee, 6:30 p.m.

Thursday committee meetings will include the annual dinner meeting of the Committee on Trauma at 6:30.

COMMITTEE ON ARRANGEMENTS AND EXECUTIVE COMMITTEE

The Chicago Committee on Arrangements and the Executive Committee for the Clinical Congress are actively at work on arrangements for the program. The membership of these committees follows:

Committee on Arrangements

Warren H. Cole, M.D., F.A.C.S., chairman
Lester R. Dragstedt, M.D., F.A.C.S., vice chairman

Michael L. Mason, M D, F A C S, secretary
 Dallas B. Phemister, M D, F A C S, president and regent
 of the College
 William E. Adams, M D, F A C S
 James J. Callahan, M D, F A C S

GENERAL AND PROGRAM COMMITTEES

The Clinical Congress general committee which
 operates under the Administrative Board of the
 College, consists of Dr. Malcolm T. MacEachern,
 chairman, Miss Eleanor K. Grimm, secretary,
 Doctors Bowman C. Crowell, Charles F. Branch,
 George H. Miller and H. Prather Saunders, and
 Mr. Edward G. Sandrok, Mr. James S. Shannon,
 and Miss Laura G. Jackson

The Clinical Congress Committee on Program
 consists of Dr. Frederick A. Collier, chairman, and
 Doctors Henry W. Cave, Evarts A. Graham, and
 Alton Ochsner

The Advisory Committee on Programs consists
 of Dr. George H. Miller, chairman, and Doctors
 Warren H. Cole, Sumner L. Koch, Michael L.
 Mason, Charles B. Puestow, Bowman C. Crowell,
 H. Prather Saunders, Charles F. Branch, and
 Malcolm T. MacEachern

MEDICAL MOTION PICTURES

The showing of medical motion pictures each
 day will again be a popular feature of the Clinical
 Congress. The latest available films on surgery
 and related subjects will be presented. Special
 showings will be arranged of medical motion pic-
 tures in the fields of ophthalmology and otorhino-
 laryngology. Both sound and silent films will be
 shown, all of which will have been approved by
 the Committee on Motion Pictures

Some of the newer medical motion pictures
 which have been or are being produced under
 Directing Committees of the College, will be pre-
 sented during the Clinical Congress. Among these
 will be the film entitled "Injuries of the Peripheral
 Nerves" directed by Dr. Loyal Davis, under a
 grant from the Johnson & Johnson Research
 Foundation. A premiere showing of this particu-
 lar film will take place as the concluding feature
 of the Monday morning General Assembly in the
 Grand Ballroom of The Stevens

AMERICAN COLLEGE OF SURGEONS

TECHNICAL AND SCIENTIFIC EXHIBITION

The Technical and Educational Exhibits will be held in the Exhibition Hall on the lower level of the Stevens. There will be represented leading manufacturers of surgical instruments, of x-ray apparatus, of sterilizers, of operating room lights, of ligatures, of dressings, of hospital apparatus and supplies of all kinds, and of pharmaceuticals, and publishers of medical books. There will also be presented exhibits depicting the work of the College.

ENTERTAINMENT FOR LADIES AND GUESTS

Wives, daughters, and other guests of surgeons attending the Clinical Congress and the Sixth Inter-American Congress of Surgery will have a well planned program of entertainment to help to make their visit to Chicago enjoyable. Mrs. Dallas B. Phenister is chairman of the entertainment committee. Assisting her are Mesdames William E. Adams, James J. Callahan, Walter W. Carroll, Warren H. Cole, Loyal Davis, M. Edward Davis, Lester R. Dragstedt, Walter G. Maddock, and Michael L. Mason.

On Monday, October 17, the first day, there will be registration all day in the lower lobby of The Stevens. There will be opportunities to meet the hostesses, to get acquainted, and to make plans to attend the events scheduled. State Street stores and shops are open until 8:30 on Monday evenings. A limited number of radio broadcast tickets will also be available on this first day.

On Tuesday at 11:00 o'clock the group will leave The Stevens for a 2-hour tour of the North Shore, concluding with luncheon at the Exmoor Country Club in Highland Park. Enroute they will see the smart Michigan Avenue specialty shops, Lincoln Park, world-famed Lake Shore Drive, Belmont Yacht Harbor, Edgewater Beach Hotel, Mundelein College, Loyola University, Northwestern University, Evanston, and other beautiful suburbs. Advance reservations are absolutely necessary for this trip.

Fortunately, St. Luke's Fashion Show occurs during Clinical Congress week. Taking advantage of this, the committee has arranged for the group to attend this event on Wednesday afternoon at 2:00 o'clock at Medinah Temple on the near North Side. This is Chicago's outstanding fashion show of the year. Bonwit-Teller, whose new five-story store on North Michigan Avenue opened in late August, will provide the stage setting for this extensive display by Chicago's leading jewelers, department stores, couturiers, etc.

Thursday afternoon at 3:00 o'clock the group will gather at the Art Institute for a tour of Mrs. James Ward Thorne's miniature rooms. Mrs.

Thorne will appear in person to tell how she produced these world famous rooms. Tea will follow on Friday afternoon at 2:00 o'clock. The group will leave The Stevens for a tour of the South Shore. Among the highlights of this tour will be the Field Museum, the Shedd Aquarium, Adler Planetarium, Art Institute, Buckingham Fountain, Chicago's old Gold Coast of 40 years ago, Soldier Field, Jackson Park, Museum of Science and Industry, Midway Plaisance, the University of Chicago, Washington Park, and the Fountain of Time by Lorado Taft.

Guests may attend any or all of these events. Reservations should be made immediately. The costs are as follows: Tuesday tour and luncheon, \$5.50; Wednesday Fashion Show, \$2.40; Thursday Art Institute tour and tea, \$1.50; Friday tour, \$2.25.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Advance registration will greatly expedite the procedure of registering. No registration fee will be charged. Fellows whose dues are paid to December 31, 1948. For endorsed Junior and Senior Candidates, the fee will be \$5.00. Non-Fellows who after individual consideration are permitted to register, will pay a fee of \$10.00. No registration fee will be required of initiates of the class of 1949.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible. In making these, communications should be addressed to the Convention Housing Bureau, 105 West Madison Street, Chicago, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations, both for surgeons and hospital representatives, are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated.

The principal participating hotels are		Single	Double

PROGRAM IN BRIEF

CLINICAL CONGRESS OF THE AMERICAN COLLEGE OF SURGEONS AND SIXTH INTER-AMERICAN CONGRESS OF SURGERY

Sunday, October 16

3 00- 6 00 Meeting, Governors

Monday, October 17

8 00-12 00 Clinics, local hospitals
10 00-12 30 General Assembly
1 00- 5 00 Clinics and Demonstrations at local hospitals
1 30- 4 00 Medical Motion Pictures
1 30- 3 00 Panel Discussion
2 00- 4 30 Television, Operations
2 00- 5 00 Forum, Fundamental Surgical Problems
2 00- 5 00 Hospital Conference
3 30- 5 00 Panel Discussion
8 15-10 30 Presidential Meeting

Tuesday, October 18

8 00-12 00 Clinics and Demonstrations at local hospitals
9 00-12 00 Forum, Fundamental Surgical Problems
9 30-12 30 Surgical Film Exhibition, General Surgery
10 00-12 00 Symposium on Amputees
10 00-12 30 Hospital Conference
10 00-12 30 Television, Operations
1 00- 5 00 Clinics and Demonstrations at local hospitals
1 30- 3 00 Panel Discussion
2 00- 5 00 Forum, Fundamental Surgical Problems
2 00- 4 00 Television, Operations
2 00- 4 30 Surgical Film Exhibition (EENT)
2 00- 5 00 Hospital Conference
2 00- 5 00 Symposium on Trauma
3 30- 5 00 Panel Discussion
7 00- 8 00 Surgical Film Exhibition (EENT)
8 00-10 00 Scientific Session, General Surgery
8 00-10 00 Scientific Session, Otorhinolaryngology
8 00-10 00 Hospital Conference

Wednesday, October 19

8 00- 9 30 Hospital Breakfast Conference
8 00-12 00 Clinics and Demonstrations at local hospitals
9 00-12 00 Forum on Fundamental Surgical Problems (2 sections)
10 00-12 00 State and Provincial Executive, Credentials and Judiciary Committees
9 30-12 30 Surgical Film Exhibition
10 00-12 30 Hospital Conference
10 00-12 30 Television
1 00- 5 00 Clinics and Demonstrations at local hospitals
1 30- 3 00 Panel Discussion
2 00- 5 00 Forum on Fundamental Surgical Problems
2 00- 4 00 Surgical Film Exhibition
2 00- 4 00 Television—Operations
2 00- 5 00 Symposium on Cancer
2 00- 5 00 Hospital Conference
3 30- 5 00 Panel Discussion
3 30- 5 30 Meeting of National and Regional Fracture Committees
7 00- 8 00 Surgical Film Exhibition, (EENT)

8 00-10 00 Scientific Session, General Surgery
8 00-10 00 Hospital Conference

Thursday, October 20

8 00- 1 30 Hospital Conference, Breakfast
8 00-12 00 Clinics and Demonstrations at local hospitals
9 00-12 00 Forum on Fundamental Surgical Problems
9 00-12 30 Surgical Film Exhibition, General Surgery
10 00-12 30 Hospital Conference
10 00-12 30 Television, Operations
1 00- 5 00 Clinics and Demonstrations at local hospitals
1 30- 3 30 Forum on Fundamental Surgical Problems
1 30- 3 30 Surgical Film Exhibition
1 00- 3 30 Seminar
2 00- 4 00 Television
2 00- 5 00 Hospital Conference
3 30- 3 45 Adjourned Meeting, Governors
3 45- 5 30 Annual Meeting of Fellows
7 00- 8 00 Surgical Film Exhibition (EENT)
8 00-10 00 Scientific Session, General Surgery
8 00-10 00 Ophthalmology
8 00-10 00 Hospital Conference

Friday, October 21

8 00-12 00 Clinics and Demonstrations at local hospitals
8 00-12 00 Tours of hospitals—hospital group
9 00-12 00 Forum on Fundamental Surgical Problems
9 30-12 30 Surgical Film Exhibition, General Surgery
10 00-12 00 Television, Operations
10 00-12 30 Inaugural Session, Inter American Congress of Surgery
12 30- 2 30 Luncheon for Delegates, Inter American Congress of Surgery
1 00- 2 30 Assembly of Initiates
1 00- 4 00 Tours of hospitals—hospital group
1 00- 5 00 Clinics and Demonstrations at local hospitals
1 30- 4.45 Panel Discussion for each of the Following
Obstetrics and Gynecology
Plastic Surgery
Neurological Surgery
Thoracic Surgery
Urology
Orthopedic Surgery
8 15-10 30 Convocation

Saturday, October 22

10 00-12 30 Scientific Session, Sixth Inter American Congress of Surgery
2 00- 5 00 Scientific Session, Inter American Congress of Surgery
7 00-11 00 Official Banquet—Inter-American Congress of Surgery

Sunday, October 23

10 00-12 30 Business Session, Inter-American Congress of Surgery
2 00- 4 00 Scientific Session, Inter American Congress of Surgery

GENERAL ASSEMBLY

JOINT SESSION—SURGEONS AND HOSPITAL REPRESENTATIVES

Monday, 10 00 a m —12 30 p m —Grand Ballroom, The Stevens

DALLAS B. PHEMISTER, M D , F A C S , Chicago, President, American College of Surgeons, Presiding
The Ever Present Challenge—Good Care of the Patient ARTHUR W. ALLEN, M D , F A C S , Boston, Vice
Chairman, Board of Regents, American College of Surgeons
The Health of the Nation—Our Greatest Asset HARRISON RAY ANDERSON, D D , Chicago, Pastor, Fourth
Presbyterian Church
The Voluntary Hospital—The Foundation of the Present Hospital System REV JOHN W. BARRETT,
Chicago, director of Catholic Hospitals, Archdiocese of Chicago, president, Catholic Hospital Asso-
ciation
Trends in Legislation Affecting Hospitals GEORGE BUGBEE, Chicago, executive director, American Hos-
pital Association
Means for Diagnostic Facilities in Community Hospitals for Service to All PAUL B. MAGNUSON, M D ,
F A C S , Washington, D C , Chief Medical Officer, Veterans Administration, Secretary, American
College of Surgeons
Premiere Showing Injuries of the Peripheral Nerves Film Directed by LOVAL DAVIS, M S , Ph D , M D ,
F A C S , Chicago, Professor of Surgery and Chairman of Division of Surgery, Northwestern University
Medical School
(Production made possible through a grant from the Johnson & Johnson Research Foundation)

PRESIDENTIAL MEETING

Monday, 8 15-10 30 p m —Grand Ballroom, The Stevens

DALLAS B. PHEMISTER, M D , F A C S , Chicago, President, American College of Surgeons, Presiding
Processional—Officers, Regents, and Distinguished Guests
Invocation
Address of Welcome
WARREN H. COLE, M D , F A C S , Chicago, Chairman, Committee on Arrangements
Introduction of Distinguished Guests
ARTHUR W. ALLEN, M D , F A C S , Boston, Vice Chairman, Board of Regents
Address of Retiring President An Evaluation of Full-Time and Group Practice for the Clinical Faculty of a
Medical School
DALLAS B. PHEMISTER, M D
Inauguration of Officers
Presented by HOWARD A. PATTERSON, M D , F A C S , New York, Retiring First Vice President
First Vice President DONALD G. TOLLEFSON, M D , F A C S , Los Angeles
Second Vice President ROBERT M. MOORE, M D , F A C S , Galveston
President FREDERICK A. COLLER, M D , F A C S , Ann Arbor

LEARMONTH, K C V O , C B E , F R C S (Ed), Edinburgh, Scotland
Recessional

EVENING SCIENTIFIC SESSIONS

GENERAL SURGERY and GYNECOLOGY and OBSTETRICS

Tuesday, 8 00-10 30 p m —Grand Ballroom—The Stevens

Symposium on Acute Surgical Emergencies in Gynecology and Obstetrics

General Introduction NEWELL W. PHILPOTT, M D , F A C S , Montreal
Tubal Pregnancy, Its Diagnosis and Treatment LEWIS C. SCHEFFEY, M D , F A C S , Philadelphia
Pelvic Peritonitis Occurring in the Obstetrical or Gynecological Patient FRANK GLENN, M D , F A C S ,
New York
Emergency Cesarean Section WILLIAM E. STUDDIFORD, M D , F A C S , New York.

Wednesday, 8 00-10 30 p m , Grand Ballroom, The Stevens

Fracture Oration Fracture Hazards OTTO J. HERMANN, M D , F A C S , Boston

Symposium on Blood Coagulation and the Use of Anticoagulants

The Significance of Different Methods for Prothrombin Estimation and Their Relative Values JOHN H OLWIN, M D, F A C S, Chicago
 Studies on Antithrombin and Etiologic Factors in Phlebothrombosis JOHN H KAY, M D, New Orleans
 A Further Report on Dicumarol Prophylaxis Against Venous Thrombosis in Women GEORGE VAN S SMITH, M D, F A C S, Brookline, Massachusetts

Thursday, 8 00-10 30 p m, Grand Ballroom, The Stevens

Symposium on Malignant Disease

Chemotherapy in Malignant Neoplastic Disease CARL V MOORE, M D, St Louis
 Hormone Therapy of Cancer CHARLES B HUGGINS, M D, Chicago
 What We Have Learned from Isotopes Concerning Depletion and Repair in Surgical Patients FRANCIS D MOORE, M D, F A C S, Boston
 The Use of Radioactive Iodine in Studying the Pathologic Physiology of Thyroid Cancer RULON W RAWSON, M D, New York

CONVOCATION

Friday, 8 15-10 30 p m —Grand Ballroom, The Stevens

FREDERICK A COLLER, M D, F A C S, Ann Arbor, President, American College of Surgeons, Presiding
 Processional—Initiates, Officers, Regents, and Distinguished Guests
 Invocation
 Presentation of Initiates for Fellowship ARTHUR W ALLEN, M D, F A C S, Boston, Vice Chairman,
 Board of Regents
 Fellowship Pledge The Initiates
 Conferring of Fellowships by the President
 FREDERICK A COLLER, M D
 Conferring of Honorary Fellowships
 The President
 Fellowship Address Science in Surgery—Stop, and Look, and Listen

 England, President, Royal College of Surgeons of England
 Recessional

PANEL DISCUSSIONS

GENERAL SURGERY

Monday, 1 30-3 00 p m

Surgical Lesions of the Breast

Moderator GEORGE G FINNEY, M D, F A C S, Baltimore
 Collaborators J MONTGOMERY DEEVER, M D, F A C S, Philadelphia, STUART W HARRINGTON,
 M D, F A C S, Rochester, Minnesota, W PERRIN NICOLSON, M D, Atlanta, HUGH H TROUT,
 M D, F A C S, Roanoke

Monday, 3 30-5 00 p m

Fractures of the Skull

Moderator ELDRIDGE H CAMPBELL, M D, F A C S, Albany
 Collaborators FRANK H. MAYFIELD, M D, F A C S, Cincinnati, DONALD MUNRO, M D, F A C S
 Boston, HARRY B WILKINS, M D, F A C S, Oklahoma City

Tuesday, 1 30-3 00 p m

Massive Upper Abdominal Hemorrhage

Moderator JOHN H MULHOLLAND, M D, F A C S, New York
 Collaborators ROBERT ELMAN, M D, F A C S, St Louis, CHARLES G JOHNSTON, M D, F A C S,
 Detroit, JOHN D STEWART, M D, F A C S, Buffalo

Tuesday, 3 30-5 00 p m

New Surgical Technics in Drug Treated Infections

Moderator CHAMP LYONS, M D, New Orleans
 Collaborators HARVEY S ALLEN, M D, F A C S, Chicago, FRANK B BERRY, M D, F A C S, New
 York, GEORGE K. CARPENTER, M D, F A C S, Nashville

AMERICAN COLLEGE OF SURGEONS

Wednesday, 1 30-3 00 p m

The Management of Acute Emergencies Occurring During Operations
 Moderator I MIMS GAGE, M D, F A C S, New Orleans
 Collaborators BENTLEY P COLCOCK, M D, F A C S, Boston, DANIEL C ELKIN, M D, F A C S,
 Atlanta, NORMAN E FREEMAN, M D, F A C S, San Francisco, CARL A MOYER, M D, F A C S,
 Dallas

Wednesday, 3 30-5 00 p m

Preoperative and Postoperative Care and Anesthesia for Infants
 Moderator THOMAS H LANMAN, M D, F A C S, Boston
 Collaborators C EVERETT KOOP, M D, Philadelphia, WILLIS J POTTS, M D, F A C S, Chicago,
 ROBERT M SMITH, M D, Boston

SURGICAL SPECIALTIES, Friday, 1 30-4 45 p m

ORTHOPEDIC SURGERY

Moderator GUY A CALDWELL, M D, F A C S, New Orleans
Management of Established Non-Union of the Long Bones
 Collaborators HUGH SMITH, M D, F A C S, Memphis, FRANK E STINCHFIELD, M D, F A C S,
 New York, ALEJANDRO VELASCO ZIMBRON, M D, Mexico City
Indications and Technic for Arthrodeses of the Joints of the Foot and Ankle in Post-Traumatic Conditions
 Collaborators HAROLD B BOYD, M D, F A C S, Memphis, JAMES A DICKSON, M D, F A C S,
 Cleveland, C LESLIE MITCHELL, M D, F A C S, Detroit

PLASTIC SURGERY

Moderator JEROME P WEBSTER, M D, F A C S, New York
Plastic Surgery and the Treatment of Malignant Skin Disease
 Collaborators JAMES BARRETT BROWN, M D, F A C S, St Louis, W BRANDON MACOMBER, M D,
 F A C S, Albany, CLAIRE L STRAITH, M D, F A C S, Detroit
The Use of Skin Homografts
 Collaborators JAMES F CONNELL, M D, Fort Sam Houston, WILLIAM P LONGMIRE, JR, M D,
 Los Angeles, BLAIR O ROGERS, M D, Minneapolis

UROLOGY

Moderator GEORGE F CAHILL, M D, F A C S, New York
Hydronephrosis Due to Upper Ureter Obstruction
 Collaborators GRAYSON L CARROLL, M D, F A C S, St Louis, FRED E B FOLEY, M D, St Paul,
 PARKE G SMITH, M D, F A C S, Cincinnati
Ureteral Intestinal Transplantation
 Collaborators CHARLES C HIGGINS, M D, F A C S, Cleveland, VICTOR F MARSHALL, M D,
 F A C S, New York, JAMES T PRIESTLY, M D, F A C S, Rochester, Minnesota

THORACIC SURGERY

Moderator BRIAN B BLADES, M D, F A C S, Washington
Surgery of the Heart and Great Vessels
 Collaborators ALFRED BLALOCK, M D, F A C S, Baltimore, ROBERT E GROSS, M D, F A C S,
 Boston, EDWARD B D NEUHAUSER, M D, Boston
Intrathoracic Tumors
 Collaborators THOMAS H BURFORD, M D, F A C S, St Louis, JOHN H GIBBON, JR, M D, F A C S,
 Philadelphia, EDWARD M KENT, M D, Pittsburgh

NEUROLOGICAL SURGERY

Moderator ALFRED W ADSON, M D, F A C S, Rochester, Minnesota
Chemical and Physical Diagnostic Aids in the Localization of Brain Tumors
 Collaborators GEORGE MOORE, M D, Minneapolis, ERIC OLDBERG, M D, F A C S, Chicago,
 BERTRAM SELVERSTONE, M D, Boston, HENDRICK J SVIEN, M D, Rochester, WILLIAM H
 SWEET, M D, Boston
Diagnosis and the Localization of Intraspinal Tumors
 Collaborators PAUL C BUCY, M D, F A C S, Chicago, T C ERICKSON, M D, Madison, HAROLD C
 VORIS, M D, F A C S, Chicago

OBSTETRICS AND GYNECOLOGY

- Moderator FRANKLIN L. PAYNE, M D, F A C S, Philadelphia
Carcinoma of the Uterine Cervix—Modern Concepts in Diagnosis and Treatment
 Collaborators ROBERT GORDON DOUGLAS, M D, New York, HERBERT F. TRAUT, M D, F A C S, San Francisco, PAUL A. YOUNGE, M D, Brookline
Cesarean Section—Should the Latitude of Its Indications be Broadened?
 Collaborators D. ANTHONY D'ESOP, M D, New York, CARL P. HUBER, M D, Indianapolis, H. HUDNALL WARE, JR., M D, F A C S, Richmond

SYMPOSIUM ON AMPUTEES

Tuesday, 10 00 a m —12 00 noon

ROBERT H. KENNEDY, M D, F A C S, New York, Chairman, Committee on Trauma, Presiding
 The Care and Education of Amputees

SYMPOSIUM ON TRAUMA

Tuesday, 2 00–5 00 p m

- ROBERT H. KENNEDY, M D, F A C S, New York, Chairman, Committee on Trauma, Presiding
 The Plastic Approach to the Surgery of Trauma TRUMAN G. BLOCKER, JR., M D, F A C S, Galveston, Professor of Plastic and Maxillo-facial Surgery, University of Texas School of Medicine
 Plastic Surgical Repair of Radiation Injuries JAMES BARRETT BROWN, M D, F A C S, St. Louis, Associate Professor of Clinical Surgery, Washington University School of Medicine
 Blood and Blood Substitutes in Trauma JONATHAN E. RHOADS, M D, F A C S, Philadelphia, Associate Professor of Surgery, University of Pennsylvania School of Medicine and Assistant Director of the Harrison Department of Surgical Research
 A Prolonged End Result Study of 235 Intracapsular Fractures of the Femoral Neck MATHER CLEVELAND, M D, F A C S, New York, Attending Orthopedic Surgeon and Director of Orthopedic Out-Patient Department, St. Luke's Hospital
 Observations on Results of Shoulder Cuff Repair HARRISON L. McLAUGHLIN, M D, F A C S, New York, Professor of Clinical Orthopedic Surgery, College of Physicians and Surgeons, Columbia University
 An Analysis of the Management and Complications of Multiple (3 or more) Rib Fractures DUNCAN A. CAMERON, M D, Detroit, Assistant Professor of Surgery, Wayne University School of Medicine
 Use of Intramedullary Fixation in Fractures HAROLD A. SOFELD, M D, F A C S, Chicago, Assistant Professor of Bone and Joint Surgery, Northwestern University Medical School
 Fractures of the Tarsal and Metatarsal Bones FRANCIS M. McKEEVER, M D, F A C S, Los Angeles, Associate Clinical Professor of Surgery (Orthopedic), University of Southern California School of Medicine

SYMPOSIUM ON CANCER

Wednesday, 2 00–5 00 p m

- GRANTLEY W. TAYLOR, M D, F A C S, Boston, Chairman, Cancer Committee, American College of Surgeons, Presiding
 Melanopitheiomas HAMILTON MONTGOMERY, M D, Rochester, Minnesota, Associate Professor of Dermatology and Syphilology, Mayo Foundation, University of Minnesota
 Benign Bone Tumors MURRAY M. COPELAND, M D, F A C S, Washington, D C, Professor of Oncology, Georgetown University School of Medicine
 Branchiogenic Cancer HAYES MARTIN, M D, F A C S, New York, Professor of Clinical Surgery, Cornell University Medical College, Attending Surgeon, Memorial Hospital for the Treatment of Cancer and Allied Diseases
 What Is a Precancerous Lesion? FRED W. STEWART, M D, New York, Professor of Pathology, Cornell University Medical College, Pathologist, Memorial Hospital for the Treatment of Cancer and Allied Diseases
 Cancer of the Kidney HERMAN L. KRETSCHMER, M D, F A C S, Chicago, Professor of Urology, University of Illinois College of Medicine, Chief, Department of Urology, Presbyterian Hospital
 Sarcomas of the Soft Parts ARTHUR PURDY STOUT, M D, New York, Professor of Surgical Pathology, Columbia University College of Physicians and Surgeons

AMERICAN COLLEGE OF SURGEONS

ANNUAL MEETING—BOARD OF GOVERNORS

Sunday, 3 00-6 00 p m —Murphy Memorial Auditorium
 HOWARD A PATTERSON, M D , F A C S , New York, First Vice President, American College of Surgeons,
 Presiding

Organization of Local Chapters of the College
 Means of Improving Conditions in the Practice of Surgery in Areas where Problems Exist, Including Dis-
 cussion of the Principles of Financial Relations in the Professional Care of the Patient
 Sectional Meetings Discussion of Their Present Value, Means through which They May Be Improved, and
 the Desirability of Arranging an Increased Number of Meetings Each Year
 Evaluation of Present Activities of the College
 Suggestions Concerning the College in General
 General Discussion

ADJOURNED MEETINGS

BOARD OF GOVERNORS OF THE COLLEGE

Wednesday, Luncheon, 12 00 p m -2 00 p m —Boulevard Room, The Stevens
 FREDERICK A COLLER, M D , F A C S , Ann Arbor, President, American College of Surgeons, Presiding
 Unfinished Business

Thursday, 3 30-3 45 p m —Grand Ballroom, The Stevens
 Report of Committee on Nominations to the Board of Governors
 Election of Regents of the College

ANNUAL MEETING, FELLOWS OF THE COLLEGE

Thursday, 3 45-5 30 p m —Grand Ballroom, The Stevens
 FREDERICK A COLLER, M D , F A C S , Ann Arbor, President, American College of Surgeons, Presiding
 Report of Committee on Nominations to the Fellows
 Election of Officers and Governors of the College

Report of the Treasurer WARREN H COLE, M D , F A C S , Chicago, Treasurer, EDWARD G SANDROK,
 Comptroller
 Cancer Committee GRANTLEY W TAYLOR, M D , F A C S , Boston, Chairman

 Medical Service in Industry BOWMAN C CROWELL, M D , Associate Director, CHARLES F BRANCH,
 M D , Assistant Director, G R HESS, M D , Assistant
 Publications ELEANOR K. GRIMM, Administrative Executive Library and Department of Literary Re-
 search L MARGUERITE PRIME, Director of Library and Department of Literary Research
 Public Relations LAURA G JACKSON, Director of Public Relations
 The American College of Surgeons Fellowship Obligations and Opportunities ARTHUR W ALLEN,
 M D , F A C S , Boston, Vice Chairman, Board of Regents

SURGICAL SEMINAR

Nutritional Problems Including a Consideration of the Use of Fluids and Electrolytes

1 00 p m , Thursday—Grand Ballroom, The Stevens

- I S RAYDIN, M D , F A C S , Philadelphia, John Rhea Barton Professor of Surgery, University of Pennsylvania Medical School, Presiding
- The Measurement of the Total Exchangeable Potassium by Isotope Dilution in Man LESLIE CORSA, JR., M D , RICHARD W STEENBERG, M D , JOHN M OLNEY, JR., M D and FRANCIS D MOORE, M D , F A C S , Boston, Massachusetts Peter Bent Brigham Hospital and Harvard Medical School
- Studies in Experimental Alkalosis ROBERT E L BERRY, M D , F A C S , VIVIAN IOB, PH D , DANIEL C THOMPSON, M D , RALPH D MAHON, M D and SAMUEL J GREER, M D , Ann Arbor, Michigan University of Michigan Medical School
- Renal Function in Relation to Operations WALTER G MADDOCK, M D , F A C S , Chicago, Ill North western University Medical School
- Water and Electrolyte Exchange in the Postoperative Patient JAMES WALKER, JR., M D and BROOKE ROBERTS, M D , Philadelphia, Pennsylvania University of Pennsylvania School of Medicine
- The Individual Essential Amino Acids in Plasma and Urine Following Surgery and in Malnutrition TILDEN C EVERSON, M D , M S , Chicago, Illinois University of Illinois College of Medicine
- The Significance of Simultaneous Caloric Intake on the Utilization of Parenteral Protein EDWIN H ELLISON, M D , ROBERT M ZOLLINGER, M D , F A C S and ROBERT S MCCLEARY, M A , M D , F A C S , Columbus, Ohio Ohio State University College of Medicine
- The Effect of Nutritional Defects in the Response to Infection PAUL CANNON, M D , Chicago, Illinois University of Chicago School of Medicine
- The Importance of Nutrition in Surgical Patients RICHARD L VARCO, M D , Minneapolis, Minnesota University of Minnesota Medical School

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

Monday 2 00 p m —5 00 p m , Tuesday, Wednesday, Thursday, 9 00 a m —12 00 m & 2 00 p m —5 00 p m and Friday, 9 00 a m —12 00 m

Gall Bladder and Pancreas, Urology, Orthopedics, Plastic Surgery

2 00 p m Monday—8th Street Theatre

- WARREN H COLE, M D , F A C S , Chicago, Professor of Surgery and Head, Department of Surgery, University of Illinois College of Medicine, Presiding
- Cholecysto-Choledochal Fistula An Unusual Form of Internal Biliary Fistula ALBERT BEHREND, M D , F A C S and MILTON L CULLEN, M D , Philadelphia, Pennsylvania University of Pennsylvania School of Medicine
- Fluorescein An Adjunct in Surgery of the Gallbladder and Biliary Passages GERALD J MENEKER, M D and MORRIS L PARKER, M D , F A C S , Chicago, Illinois Michael Reese Hospital
- Healing in the Common Bile Duct An Experimental Study THOMAS C DOUGLASS, M D , F A C S , BENJAMIN F LOUNSBURY, M D , NICHOLAS WETZEL, M D and WILLIAM W CUTTER, M D , Chicago, Illinois Northwestern University School of Medicine
- Liver Protein Regeneration in the Presence of Biliary Obstruction COLIN G FERGUSON, M D , CHARLES S ROGERS, M D and HARRY M VARS, PH D , Philadelphia, Pennsylvania University of Pennsylvania School of Medicine
- Studies on External Pancreatic Secretion with Chronic Pancreatic Fistula with Emphasis on the Effects of Vagotomy E F ROUTLEY, M D , F G MANN, M D , M S , D Sc , J L BOLLMAN, M S , B S , M D , J H GRINDLAY, M D , M S (SURG), F A C S , and E V FLOCK, M S , PH D , Rochester, Minnesota Mayo Foundation
- Report on Splanchicectomy for Fibrocystic Disease of Pancreas WILLIAM AYERS, M D , DANIEL STOWENS, M D and ALTON OCHSNER, M D , F A C S , New Orleans, Louisiana Tulane University of Louisiana School of Medicine
- Studies on Phospholipid Metabolism in Normal and Depancreatized Dogs Using Radioactive Phosphorus WILEY F BARKER, M D and ERIC ROGERS, M D , Boston, Massachusetts Harvard Medical School and Peter Bent Brigham Hospital
- Prevention and Dissolution of Experimental Urinary Calculi by Diuresis WILLIAM J GROVE, M D and C W VERMEULEN, M D , Chicago, Illinois University of Illinois College of Medicine
- A Method for the Study of Urinary Calcium and Urinary Phosphorus in the Normal and Diseased Kidney R H FLOCKS, M D , F A C S , JOHN TUDOR, M D and MARGARET JOHNSON, B S , Iowa City, Iowa State University of Iowa College of Medicine

AMERICAN COLLEGE OF SURGEONS

The Endocrine Basis for Slipping of the Upper Femoral Epiphysis An Experimental Study W ROBERT HARRIS, M D, Toronto, Ontario University of Toronto Faculty of Medicine
Experimental Evaluation of Homogenous Bone Grafts FRED C REYNOLDS, M D, F A C S and DAVID R OLIVER, St Louis, Missouri Washington University School of Medicine
The Production of Epithelial Lined Tubes from Buried Strips of Intact Skin WILLIAM J BUTLER, M D, F A C S and WAYNE WHITAKER, Ph D, Ann Arbor, Michigan University of Michigan Medical School
Nicotinic Acid and Epinephrine Test for Determining the Source of Blood Supply of Delayed Skin Flaps GEORGE OLANDER, M D, Chicago, Illinois University of Illinois College of Medicine and Hines Veterans Hospital

Surgery of the Heart

9 00 a m, Tuesday—Grand Ballroom, The Stevens

ROBERT E GROSS, M D, F A C S, Boston, Assistant Professor of Surgery, Harvard Medical School, Presiding
The Vagus Nerve in Cardiac Arrest HERBERT E SLOAN, M D, Ann Arbor, Michigan University of Michigan Medical School
Determination of Electrical Currents Which Will Produce Fibrillation and Defibrillation in Dogs KENNETH MOOSLIN, M D, STUART MCKAY, Ph D and SANFORD E LEEDS, M D, F A C S, San Francisco, California Mount Zion Hospital
The Production of Progressive Coronary Artery Narrowing in Dogs WILLIAM T FITTS, JR, M D, WARNER F SHELDON, M D and JOHN J SAYON, M D, Philadelphia, Pennsylvania University of Pennsylvania College of Medicine
Observations on the Growth of Aortic Anastomoses in Puppies ELLIOTT S HERWITT, M D, F A C S and SIGMUND A BRAHMS, M D, New York, New York The Mt Sinai Hospital
A Technique for the Complete Excision of a Portion of the Ventricle of the Heart BRUCE G MACMILLAN, M D, B N CARTER, M D, Ph D, F A C S, Cincinnati, Ohio University of Cincinnati College of Medicine
Excision of Cardiac Infarcts MILTON C MALONEY, M D and W EMORY BURNETT, M D, F A C S, Philadelphia, Pennsylvania Temple University College of Medicine
Commissurotomy for Mitral Stenosis R P GLOVER, M D, C P BAILEY, M D, M Sc, F A C S, and T J E O'NEILL, M D, Philadelphia, Pennsylvania The Hahnemann Medical College and Hospital of Philadelphia
Experimental Production and Closure of Cardiac Interventricular Septum Defects MAURICE GALANTE, M D, ROBERT JOHANSEN, M D, RICHARD E GARDNER, M D, H BRODIE STEPHENS, M D and H J McCORKLE, M D, F A C S, San Francisco, California University of California Medical School
Experimental Production of Interventricular Septal Defects in Dogs and Certain Physiologic Effects GEORGE D J GRIFFIN, JR M D, and HIRAM E ESSEX, M D, Rochester, Minnesota Mayo Foundation
An Experimental Method for Producing Lesions at Selected Sites in the Mitral Valve in Dogs DUANE L MERRILL, M D, Baltimore, Maryland Johns Hopkins University School of Medicine
Plastic Valvular Prostheses CHARLES A HUFNAGEL, M D, Boston, Massachusetts Peter Bent Brigham Hospital and Harvard Medical School
Observations of the Action of a Pump Designed to Shunt the Venous Blood Past the Right Heart Directly into the Pulmonary Artery WILLIAM H SEWELL, JR and WILLIAM W L GLENN, M D, New Haven, Connecticut Yale University School of Medicine
Pump Oxygenator to Support the Systemic Circulation During the Surgical Approach to the Heart CLARENCE DENNIS, M D, KARL E KARLSON and DAVID SANDERSON, Minneapolis, Minnesota University of Minnesota Medical School

Vascular Surgery and Surgery of Hypertension

2 00 p m, Tuesday—North Ballroom, The Stevens

LOYAL DAVIS, M D, F A C S, Chicago, Illinois, Professor of Surgery and Chairman of Division of Surgery, Northwestern University Medical School, Presiding
Observations of Lower Leg Venous Pressures in the Human Standing and Walking PAUL T DeCAMP, M D, N DONALD FEIBLEMAN, M D and CHARLES J RAY, M D, New Orleans, Louisiana Tulane University of Louisiana School of Medicine
Renal Function in Coarctation of the Aorta HAROLD G BARKER, M D and JOHN K CLARK, Philadelphia, Pennsylvania University of Pennsylvania School of Medicine
Repetitive Studies of Intra-Arterial Pressures After Resection of Coarctation of the Aorta in Man BOWEN E TAYLOR, M D, C T CLAGETT, M D, M S (SURG), F A C S, H B BURCHELL M D, Ph D, and E H WOOD, M D, M S, Ph D, Rochester, Minnesota Mayo Foundation
Regional Heparinization in Vascular Surgery NORMAN E FREEMAN, M D, F A C S, San Francisco, California Franklin Hospital

- Absorbable Sutures in the Surgery of Major Blood Vessels SIDNEY SMITH, M D , FRANK R JOHNSON, M D and WILLIAM L RIKER, M D , Chicago, Illinois Northwestern University Medical School
- Use of Arteriovenous Shunts for Revascularization of the Ischemic Limbs PRESCOTT JORDAN, M D and CHARLES G JOHNSTON, M D , F A C S , Detroit, Michigan, Wayne University College of Medicine
- Preservation of Arterial Grafts in Solutions Containing Antibiotics Experimental Observations HAROLD RHEINLANDER, M D and ROBERT E GROSS, M D , F A C S , Boston, Massachusetts Harvard Medical School and The Children's Hospital
- Arterial Homografts HOWARD T ROBERTSON, M D , MARVIN JOHNSON, M D , HENRY SWAN, M D , F A C S , Denver, Colorado University of Colorado Medical Center
- The Fate of the Arterial Graft in Small Arteries HARRY H MILLER, M D , ALLAN D GALLOW, M D and C STUART WELCH, M D , M S , Ph.D , F A C S , Boston, Massachusetts, Tufts Medical College and New England Center Hospital
- Reconstruction of the Superior Mesenteric Vascular Axis in Dogs ARNOLD J KREMEN, M D and LOREN NELSON, M D , Minneapolis, Minnesota University of Minnesota Medical School
- Radioactive Isotope Index of Circulation in the Selection of Patients for Sympathectomy W INDECK, M D , M T FRIEDEL, M D , M S (SURG), F A C S and F SCHAFFNER, Chicago, Illinois Hektoen Institute for Medical Research of Cook County Hospital, Stritch School of Medicine of Loyola University and The Peripheral Vascular Clinic of Mercy Hospital
- Reflex Peripheral Vasoconstriction Its Use in the Study of Patients Before and After Limb Sympathectomy CHARLES W ROBERTSON, M D , DOUGLAS A FARMER, M D and REGINALD H. SMITHWICK, M D , F A C S , Boston, Massachusetts Boston University School of Medicine
- The Use of Nor-Epinephrine as a Pressor Drug with Special Reference to Thoraco-Lumbar Sympathectomy R A DETERLING, M D , VIRGINIA APGAR, M D and MARCEL GOLDENBERG, M D , New York, New York Columbia University College of Physicians and Surgeons and Presbyterian Hospital

Neurosurgery

9 00 a m , Wednesday—8th Street Theatre

- HOWARD C NAFFZIGER, M D , F A C S , San Francisco, Professor of Surgery, University of California Medical School, Presiding
- The Transplantation of Tumors of the Human Central Nervous System into Animal Hosts JOHN MARTIN, M D , M S , Ph D , F A C S , Chicago, Illinois Northwestern University Medical School
- Extradural Hemorrhage—A Report of One Hundred Patients JOHN P GALLAGHER, M D , Washington, D C and E J BR WDER, M D , Brooklyn, New York
- Effect on Intracranial Pressure in Man of Newer Drugs and Hypertonic Solutions LOUIS BACKAY, M D and WILLIAM H SWEET, M D , Boston, Massachusetts Harvard Medical School
- Studies on the Sacral Reflex and in Paraplegia III Clinical Observations on Inhibitory Impulses Within the Sacral Reflex Arc ARNOLD M MEIROWSKY, M D and C DAVID SCHEIBERT, M D , Memphis, Tennessee Kennedy Veterans Administration Hospital
- Myelographic Demonstration of Avulsing Injuries of the Brachial Plexus A Method of Determining the Point of Injury and the Possibility of Repair FRANCIS MURPHEY, M D , Memphis, Tennessee, University of Tennessee College of Medicine, and JOHN W KIRKLIN, M D , Rochester, Minnesota Mayo Foundation
- Studies in Intracranial Pressure of Head Injuries I Basic Physiologic Observations FRANK F ESPEY, M D , HENRY W RYDER, M D , F VATNAR KRISTOFF, M D and JOSEPH P EVANS, M D , Ph D , F A C S , Cincinnati, Ohio University of Cincinnati College of Medicine
- Mesencephalo-Thalamotomy for the Treatment of Intractable Pain HENRY T WYCIS, M D , M S , F A C S and E A SPIEGEL, Philadelphia, Pennsylvania Temple University School of Medicine
- Carotid-Internal Jugular Anastomosis in the Monkey Certain Physiological Observations E S GURDJIAN, M S , Ph D , M D , F A C S and J E WEBSTER, M D , Detroit, Michigan Wayne University College of Medicine
- The Results of the Treatment of Cerebro-Vascular Accidents by Interruption of Cervical Sympathetic Impulses AVERILL STOWELL, M D , F A C S , Tulsa, Oklahoma Springer Clinic
- Topectomy Bifrontal Limited Cortical Ablation for the Treatment of Mental Illness J LAWRENCE POOL, M D , F A C S , New York, New York Columbia University College of Physicians and Surgeons
- The Usefulness of Radio-Active Substances in Studying Certain Aspects of Circulation in the Brain EDWARD B SCHLESINGER, M D and EDITH QUIMBY, M D , New York, New York Neurological Institute, Presbyterian Hospital
- Studies Upon the Altered Physiology of the Brain in Toxemias of Pregnancy MILTON L MCCALL, M D , F A C S and T VERNON FINCH, M D , Philadelphia, Pennsylvania Jefferson Medical College of Philadelphia
- A Method of Chronic Remote Electrical Stimulation of Nerves in Unanesthetized Animals JOHN J FARRELL, M D , Albany, New York Albany Medical College

*Thyroid, Lungs, Esophagus and Anesthesia**9 00 a m , Wednesday—Grand Ballroom, The Stevens*

- OWEN H WANGENSTEEN, M D , F A C S , Minneapolis, Professor of Surgery, University of Minnesota Medical School, Presiding
- The Uptake of Radioactive Iodine in Residual Thyroid Tissue Following Subtotal Thyroidectomy H. J. McCORKLE, M D , F A C S , EARL MILLER, M D , RICHARD GARDNER, M D , ROBERT JOHANSEN, M D (Presenter), MAURICE GALANTE, M D , KENNETH SCOTT, Ph D and MAYO SOLEY, M D , San Francisco, California University of California Medical School
- Experimental Study of the Effect of Occlusion of the Bronchial Arteries F HENRY ELLIS, JR , M D , JOHN H GRINDLAY, M D , M S (SURG), F A C S and JESSE E EDWARDS, M D , Rochester, Minnesota Mayo Foundation
- The Surgical Treatment of Intractable Bronchial Asthma T J E O'NEILL, M D , R P GLOVER, M D , and C P BAILEY, M D , M S , F A C S , Philadelphia, Pennsylvania The Hahnemann Medical College and Hospital of Philadelphia
- Physiological Studies in Children Following Pulmonary Resection RICHARD M PETERS, M D , ALBERT ROOS, M D and HARRISON BLACK, M D , St Louis, Missouri Washington University School of Medicine
- Use of the Mass Spectrometer in a Comparison of the Open and Closed Circuit Methods for Measuring Lung Volume ALLAN HEMINGWAY, M D , A O C NIER, M D , FLETCHER MILLER, M D , RICHARD L VARCO, M D , Minneapolis, Minnesota University of Minnesota Medical School
- The Use of Pre- and Postoperative Pulmonary Function Tests in Thoracic Surgery WILLIAM S BLAKEMORE, M D , Philadelphia, Pennsylvania University of Pennsylvania School of Medicine
- Controlled Respiration in Thoracic Surgery JOSEPH W STAYMAN, JR , M D , JOHN H. GIBBON, JR , M D , F A C S and FRANK F ALLBRITTON, JR , M D , F A C S , Philadelphia, Pennsylvania Jefferson Medical College of Philadelphia
- Effects of Positive Respiratory Pressure Upon the Circulation and Acid Base Balance of Open Chest Dogs A Comparison of Continuous with Phasic Lung Inflation and a Description of an Apparatus for the Application of Positive Pressure During Inspiration ALVIN M CAHAN, M D , HOWARD A FRANK, M D , F A C S and HENRY BANKS, B A , M D , Boston, Massachusetts Beth Israel Hospital
- Problems in Esophageal Anastomosis R W POSTLETHWAIT, M D , W RALPH DEATON, JR , M D (Presenter), H H BRADSHAW, M D , F A C S and R W WILLIAMS, Winston-Salem, North Carolina Bowman Gray School of Medicine of Wake Forest College
- The Extent to Which One May Interfere with the Blood Supply of the Esophagus and Obtain Healing on Anastomosis JOHN R PAINE, M D , JOSEPH T DAMERON, M D and JOSEPH E MACMANUS, M D , F A C S , Buffalo, New York Buffalo General Hospital and University of Buffalo School of Medicine
- The Use of Polyethylene in Reconstruction of Esophageal and Pharyngeal Defects CALVIN T KLOPF, M D , F A C S and HOWARD C PIERPONT, M D , Washington, D C George Washington University School of Medicine
- Renal and Hepatic Function Measured by Clearance and Venous Catheterization Techniques During Anesthesia and Surgery DAVID V HABIF, M D , W D BLAKE and S E BRADLEY, M D , New York, New York Columbia University College of Physicians and Surgeons
- An Analysis of the Effects of Spinal Anesthesia on Human Circulation B D KING, M D , L H PETERSON, A B , F E GREIFENSTEIN, M D and R D DRIPPS, A B , M D , Philadelphia, Pennsylvania University of Pennsylvania School of Medicine

*Stomach and Intestines**2 00 p m , Wednesday—North Ballroom, The Stevens*

- LESTER R DRAGSTEDT, M D , F A C S , Chicago, Professor and Chairman, Department of Surgery, University of Chicago School of Medicine, Presiding
- A Contribution to the Role of the Autonomic Nervous System in Gastric Secretion PAUL W SCHAFER, M D and C FREDERICK KITTLE, M D (Presenter), Kansas City, Kansas University of Kansas Medical Center
- A Study of the Extrinsic Nerve Supply Regulating Gastrointestinal Activity ROBERT M WHITROCK, M D and HENRY L TIECHE, M D , Ann Arbor, Michigan University of Michigan Medical School
- A Quantitative Study of the Effect of Vagotomy on Gastric Secretion in Total Pouch Dogs EDWARD R WOODWARD, M D , PAUL V HARPER, JR and LESTER R DRAGSTEDT, M S , Ph D , M D , F A C S , Chicago, Illinois University of Chicago School of Medicine
- Effect of Sympathetic and Parasympathetic Nerves on the Gastric Secretory Response of Total Pouch Dogs F JOHN LEWIS, M D , Minneapolis, Minnesota University of Minnesota Medical School
- The Effects of Lumbodorsal Splanchnicectomy Alone and Combined with Minimal Gastric Resection on the Gastric Secretory Mechanism JOHN J KNEISEL, M D , CHESTER W HOWE, M D , F A C S , PAUL F WARE, M D and REGINALD H SMITHWICK, M D , F A C S , Boston, Massachusetts Boston University School of Medicine and Massachusetts Memorial Hospitals

- Study of a Few Painful Gastrointestinal Disorders and Treatment by Celiac and Superior Mesenteric Ganglionectomy or by Vagotomy KEITH S GRIMSON, M D, F A C S, FRANK H LONGINO, M D, EUGENE J LINBERG and CHARLES E KERNODLE, M D, Durham, North Carolina Duke University School of Medicine
- Pathologic and Physiologic Effects of the Administration of Finely Ground Sand and Talc STEPHEN CHESSE, M D, DOROTHY CHESSE, M D, GEORGE OLANDER, M D and WILLIAM BANNER, M D, Chicago, Illinois University of Illinois College of Medicine
- The Use of Pancreatin in Reducing the Increased Fecal Nitrogen and Fecal Fat Loss Occurring After Total Gastrectomy TILDEN C EVERSON, M D, M S, MORTON I GROSSMAN, M D, PH D and ANDREW C IVY, M D, PH D, Chicago, Illinois, University of Illinois College of Medicine
- The Pathologic Distribution of Water and Electrolytes and the Loss of Red Cell Mass in Patients Following Perforated Duodenal Ulcer The Significance of the Findings to the Plan of Fluid Therapy JAMES R HOPKIRK, M D and OLIVER COPE, M D, F A C S, Boston, Massachusetts Harvard Medical School
- Identification of the Toxin of the Clostridium Organisms From Experimental Intestinal Obstruction RAYMOND E ANDERSON, M D and CARLOS A TANTURI, M D, Chicago, Illinois Northwestern University Medical School
- The Role of Clostridium Welchii in Strangulation Obstruction ISIDORE COHN, JR, M D and H R HAWTHORNE, M D, F A C S, Philadelphia, Pennsylvania University of Pennsylvania School of Medicine
- Experimental Evidence of Factors Concerned in the Viability and Eventual Recovery of Strangulated Intestine HAROLD LAUFMAN, M D, PH D, F A C S and HAROLD METHOD, M D, Chicago, Illinois Northwestern University Medical School
- The Use of Antibiotics in Experimental Closed Loop Obstruction in Small Bowel E B TOVEE, M D and MURRAY FLOCK, M D, Toronto, Ontario University of Toronto Faculty of Medicine

Wounds and Wound Healing, Burns, Infections and Shock

9 00 a m, Thursday—Grand Ballroom, The Stevens

- MICHAEL L MASON, M D, F A C S, Chicago, Associate Professor of Surgery, Northwestern University Medical School, Presiding
- Studies in Experimental Frostbite JOSEPH C FINNERAN, M D and HARRIS B SHUMACKER, JR, M D, Indianapolis, Indiana Indiana University Medical Center
- Tissue Reactions to Waxes Derived From Spool Cotton Their Possible Relation to Suture Granulomata and Suture Extrusion NORMAN ROSENBERG, M D, F A C S, SYLVAN E MOOLTEN, M D, F A C P and LEO VROMAN, New Brunswick, New Jersey St Peter's General Hospital
- Experimental Study of the Rate of Healing of Tendon Grafts HARVEY S ALLEN, M D, F A C S, Chicago, Illinois Northwestern University Medical School
- Urine and Fecal Urobilinogen Excretion in Severe Burns G WATSON JAMES III, M D, O J PURNELL, M D and EVERETT IDRIS EVANS, B S, PH D, M D, F A C S, Richmond, Virginia Medical College of Virginia
- Experimental Study of the Effect of Heparinization and Gravity on Tissue Loss in Thermal Burns J ROBERT PARSONS, JR, M D, E MEREDITH ALDRICH, M D, M S (SURG), F A C S and EDWIN P LEHMAN, M D, F A C S, Charlottesville, Virginia University of Virginia Department of Medicine
- Chloromycetin In Surgical Infections JEROME GIUSEFFI, M D and W A ALTEMEIER, M D, M S, F A C S, Cincinnati, Ohio University of Cincinnati College of Medicine
- The Appropriate Selection of Antibacterial Agents Evaluation of a Rapid Sensitivity Test CHESTER W HOWE, M D, F A C S and DOROTHEA J REILLY, M A, Boston, Massachusetts Boston University School of Medicine
- Completed Clinical Study of the Use of Hexachlorophene (G-11) in Phisoderm for Disinfection of the Skin BROMLEY S FREEMAN, M D, F A C S and THOMAS K. YOUNG, JR., M D, Temple, Texas McCloskey Veterans Administration Hospital
- A New Separation of Several Sets of Pathologic Mechanisms Which Occur During Different Kinds of Circulatory "Shock" M H KNISELY, L A CRANDAL, JR, S BARKER, E H BLOCH, A LIPSCOMBE, L WARNER, F BROOKS and L R DRAGSTEDT, M S, PH D, M D, F A C S Charleston S C, Medical College of the State of South Carolina, Memphis, Tennessee, University of Tennessee Medical School, and Chicago, Illinois, University of Chicago School of Medicine
- The Role of the Hypothalamus in the Pituitary-Adrenal Cortical Response to Stress DAVID M HUMF, M D, Boston, Massachusetts Peter Bent Brigham Hospital and Harvard Medical School
- Effect of Sublethal Hemorrhage and Quantitative Replacement of Whole Blood on Circulating Blood Volume FRANK W SPICER, JR, M D, IRVING RUDMAN, M D, TYGE SONDERGAARD, M D, CARROL SHAVER, M D and JOHN D STEWART, M D, Buffalo, New York University of Buffalo Medical School and Edward J Meyer Memorial Hospital

AMERICAN COLLEGE OF SURGEONS

Capillary Permeability in Shock PHILIP B PRICE, M D, F A C S, RALPH L TINGEY, M D and FRANK K INUI, M D, Salt Lake City, Utah University of Utah College of Medicine
 Effect of Intramtestinal Oxygen Insufflation on Portal and Hepatic Venous Oxygen Level in Hemorrhagic Shock THOMAS W GORMAN, M D, Montreal, Quebec McGill University Faculty of Medicine
 Some Effects of Certain Drugs on the Vessels of the Cerebral Cortex of the Dog Mensuration of Vessel Caliber as Demonstrated Photographically Through an Arcylic Window DONALD B SWEENEY, M D and DOUGLAS W EASTWOOD, M D, Iowa City, Iowa Iowa University College of Medicine

1 00 p m, Thursday—Grand Ballroom, The Stevens
 See separate program for Surgical Seminar Nutritional Problems Including a Consideration of the Use of Fluids and Electrolytes

9 00 a m, Friday—Grand Ballroom, The Stevens
 Blood and Body Fluids, Porto-Caval Anastomosis and Cancer
 HARRY A OBERHELMAN, M D, F A C S, Chicago, Professor and Chairman, Department of Surgery, Stritch School of Medicine of Loyola University, Presiding
 Alterations in Coagulation Mechanism of the Blood in Postoperative Patients RICHARD WARREN, M D, F A C S, MARY A AMDUR, PH D, JOHN BELKO, M S and DONALD V BAKER, M D, Boston, Massachusetts Veterans Administration Hospital, West Roxbury and Harvard Medical School
 Some Potential Dangers in Hypodermoclysis WATTS R WEBB, M D, and R. A LEMMER, M D, St Louis, Missouri Washington University School of Medicine
 The Use of Iodinated Plasma Protein in the Study of Blood Volumes WILLIAM D HOLDEN, M D, F A C S, JOHN P STORASSLI, M D, HYMER L FRIEDEL, M D and HARVEY KRIEGER, M D, Cleveland Ohio Western Reserve University School of Medicine and University Hospitals of Cleveland
 The Application of Paper Partition Chromatography to the Analysis of Amino Acids in Animal Tissues and Body Fluids HARRIET A DAVIS, B A, Rochester, New York University of Rochester School of Medicine and Dentistry
 Total Body Water Determination with Deuterium Oxide (Heavy Water) PAUL R SCHLOERB, M D, BENT J FRIIS-HANSEN, M D, ISIDORE S EDELMAN, M D and FRANCIS D MOORE, M D, F A C S, Boston, Massachusetts Peter Bent Brigham Hospital and Harvard Medical School
 The Spectroscopic Analysis of Body Fluids EDGAR J POTH, M A, M D, PH.D, F A C S and VICTOR W NOWINSKI, PH D, Galveston, Texas University of Texas Medical Branch
 Hepatic Function Measured by Clearance and Venous Catheterization Techniques Before and After Portocaval Anastomosis in Patients with Hepatic Cirrhosis A I S MACPHERSON, M B, CH B, F R C S E, J L BRANDT, P F ALPHONSO, A H BLAKEMORE, M D and S E BRADLEY, M D, New York, New York Columbia University College of Physicians and Surgeons
 Amino Acid Tolerance in Experimental Portocaval Anastomosis HAROLD HARPER, PH D, RICHARD E GARDNER, M D (Presenter), ROBERT JOHANSEN, M D, MAURICE GALANTE, M D and H J McCORKLE, M D, F A C S, San Francisco, California University of California Medical School
 Experimental Hepatic-Portal Arteriovenous Fistulae J A SCHILLING, M D, F W MCKEE, M D and W WILT, M D, Rochester, New York University of Rochester School of Medicine and Dentistry
 Visualization of Regional Lymph Nodes by Means of a Vital Staining Dye as an Aid in Radical Gastrectomy JOSEPH WEINBERG, M D, M Sc, F A C S and E M GREANEY, M D, Los Angeles Birmingham Veterans Administration Hospital, Van Nuys, California and University of California Medical School
 Steroids and Radiation Sensitivity J B GRAHAM, M D and R M GRAHAM, Portland, Oregon University of Oregon Medical School
 Auxiliary Carcinogens EDWARD L HOWES, M D, M S (MED), D Sc, F A C S, New York, New York Columbia University College of Physicians and Surgeons

TWENTY-EIGHTH ANNUAL HOSPITAL STANDARDIZATION CONFERENCE—

Monday, 10 00 a m—12 30 p m

GENERAL ASSEMBLY

DALLAS B. PHEMISTER, M D, F A C S, Chicago, president, American College of Surgeons, Presiding
The Ever Present Challenge—Good Care of the Patient
ARTHUR W. ALLEN, M D, F A C S, Boston, vice chairman, Board of Regents, American College of Surgeons
The Health of the Nation—Our Greatest Asset HARRISON RAY ANDERSON, D D, Chicago, Pastor, Fourth Presbyterian Church

The Voluntary Hospital—The Foundation of the Present Hospital System REV JOHN W. BARRETT, Chicago, director of Catholic Hospitals, Archdiocese of Chicago, president, Catholic Hospital Association

Trends in Legislation Affecting Hospitals GEORGE BUGBEE, Chicago, executive director, American Hospital Association

Means for Diagnostic Facilities in Community Hospitals for Service to All PAUL B. MAGNUSON, M D, F A C S, Washington, D C, chief medical officer, Veterans Administration, Secretary, American College of Surgeons

Premiere Showing Injuries of the Peripheral Nerves Film Directed by LOYAL DAVIS, M S, PH D, M D, F A C S, Chicago, Professor of Surgery and Chairman of Division of Surgery, Northwestern University Medical School
(Production made possible through a grant from the Johnson & Johnson Research Foundation)

Monday, 2 00—5 00 p m

Panel Discussion—Standards of Professional Services for the Good Care of the Patient as Rendered by
The Radiologist, the Pathologist, the Anesthesiologist, the Physical Therapist

Tuesday, 10 00 a m—12 30 p m

Standards for the Institutional Care of Psychiatric Patients in Mental Hospitals, General Hospitals, Tuberculous Patients in Sanatoria, General Hospitals

Tuesday, 2 00—5 00 p m

The Medical Staff of the Hospital Basic Considerations in Organization, Duties and Responsibilities, Essentials of Adequate Medical Staff Organization, Control of Professional Work, Review and Analysis of Clinical Work

Tuesday, 7 30—10 00 p m

Special Collaborative Conference for Doctors, Hospital Trustees and Administrators

Theme Understanding and Cooperation from the standpoint of the Doctor, the Trustee, and the Administrator

Wednesday, 8 00—9 30 a m

Breakfast Conference on Public Relations—Joint Session for Press and Radio Representatives and Hospital and Medical Personnel

Wednesday, 10 00 a m—12 30 p m

Theme—Hospital Costs and Maintenance of Standards
Present and Future Trends in Hospital Costs, Financial Responsibility for the Indigent, Blue Cross and Blue Shield Plans as Factors in Relieving the Hospital's Financial Burden

Wednesday, 2 00—5 00 p m

Standards of Professional Services for the Efficient Care of the Patient in the Hospital

Discussion based upon American College of Surgeons' Standards, and from the standpoints of Medical Staff Organization, Medical Records, Surgical Department, Medical Department, Obstetrical Department, Anesthesia Department

Wednesday, 8 00—10 00 p m

Discussion Conference with the Field Staff of the American College of Surgeons on the Activities of the College as they Affect Hospitals

Hospital Standardization and Point Rating, Graduate Training in Surgery, Medical Service in Industry, Library and Department of Literary Research, Medical Motion Pictures, Sectional Meetings, Committee on Trauma, Cancer Committee, Publications, Public Relations

Thursday, 8 00—9 30 a m

Breakfast Conference for Graduates and Administrative Residents of University Programs in Hospital Administration, and Course Directors

Experience Exchange My First Year of Administering a Hospital

Thursday, 10 00 a m—12 30 p m

Theme—Discussion of Current Problems in Hospitals

General Practice Division, Methods of Improving Medical Records, Dental Service, the Administrator and the Atom, Problems of the Small Hospital

Thursday, 2 00—5 00 p m

Forum on Trends in Hospital Administration, New Ideas and Special Hospital Problems

Selected topics from transcripts of graduates in hospital administration and administrative residents

Thursday, 8 00—10 00 p m

Open Forum on Nursing

Representatives of American Medical Association, American Hospital Association, American College of Surgeons, American College of Physicians, Catholic Hospital Association, American Protestant Hospital Association, American Nurses' Association, National League of Nursing Education, United States Public Health Service, U S Veterans Administration

Friday, 10 00 a m—12 00 Noon

and 2 00—5 00 p m

Demonstrations in Selected Chicago Hospitals

Arrangements will be made for hospital representatives to visit Chicago Hospitals for special features in which they are particularly interested

Workshop Conference with Field Staff of the American College of Surgeons on the Point Rating System method of evaluating hospitals

AMERICAN COLLEGE OF SURGEONS

COLOR TELEVISION FROM ST LUKE'S HOSPITAL

Normandy Lounge, The Stevens

1 30-2 15 General Surgery Thyroidectomy H. I. MEYER.
2 15-3 15 Plastic Surgery Skin Grafting Operation
PAUL GREELEY
3 30-4 30 General Surgery Appendectomy JOHN PRIB-
BLE

Wednesday
8 30-9 15 General Surgery Subtotal Gastric Resection
FOSTER L. McMILLAN and ASSOCIATES

9 15-10 00 General Surgery Cholecystectomy E. LEE
STROHL and ASSOCIATES
10 15-11 00 General Surgery McArthur Autoplastic
Herniorrhaphy W. G. DIFFENBAUGH
11 15-12 00 General Surgery Common Bile Duct Ex-
ploration CARL IRENEUS
1 30-2 00 General Surgery Right Hemicolectomy GUY
PONTIUS and ASSOCIATES
2 15-4 30 General Surgery Esophageal Resection JOHN
REYNOLDS

Thursday
8 30-10 15 Thoracic Surgery Pneumonectomy WILLARD
VAN HAZEL
10 30-11 00 General Surgery Lumbodorsal Sympathec-
tomy GEZA DE TAKATS
1 30-2 00 Orthopedic Surgery Triple Arthrodesis of
Ankle CLAUDE N. LAMBERT
2 15-3 15 Orthopedic Surgery Cartilage Cup Arthro-
plasty of Hip FREMONT CHANDLER
3 30-4 30 Orthopedic Surgery Arthrotomy of Knee.
JOHN NORCROSS

Friday
8 30-9 15 General Surgery Radical Mastectomy CHARLES
SHANNON and ASSOCIATES
9 30-10 00 General Surgery Femoral Herniorrhaphy
JOHN LINDQUIST
10 15-11 00 General Surgery Hand Reconstruction
Operation W. F. LYON and BURTON KILBOURNE
11 15-12 00 General Surgery Leg Amputation with Re-
inflation Anesthesia H. E. Mock, Jr.

PRELIMINARY CLINICAL PROGRAM

CLINICS IN CHICAGO HOSPITALS

This program will be superseded by the final program of clinics which will be published in the *Clinical Bulletin* which will be distributed each day at the Registration Desk during the Clinical Congress

The participating hospitals and the hospital representatives are listed in a preceding section

AUGUSTANA HOSPITAL

Tuesday

8 00-1 00 *General Surgery* Operative Clinic
Selected cases NELSON M PERCY, OSCAR E NADEAU

Wednesday

8 00-10 00 *General Surgery* Operative Clinic
Selected cases JOHN W NUZUM, EARL GARSIDE
10 00-12 00 *Neurosurgery* Operative and Nonoperative Clinic
Sympathectomy in Treatment of Pain WESLEY A GUSTAFSON

10 00-12 00 *Gynecology* Operative and Nonoperative Clinic
Complete Hysterectomy WILLIAM H BROWNE

Thursday

8 00-1 00 *General Surgery* Operative Clinic
Selected cases NELSON M PERCY, OSCAR E NADEAU

ALBERT MERRITT BILLINGS HOSPITAL

Tuesday

8 00-12 00 *General Surgery* Operative Clinics
Vagotomy LESTER R DRAGSTEDT
Carcinoma of Stomach WILLIAM E ADAMS
8 00-12 00 *Neurosurgery* Operative Clinic.
Craniotomy THEODORE RASMUSSEN
8 00-12 00 *Orthopedic Surgery* Nonoperative Clinic
Grand Rounds HOWARD C HATCHER
1 00-4 00 *Ophthalmology* Operative Clinics
Cataract Extraction External Rectus Recession AR LINGTON C KRAUSE

Wednesday

8 00-12 00 *General Surgery* Operative Clinics
Carcinoma of the Large Bowel LESTER R DRAGSTEDT
Coarctation of Aorta WILLIAM E ADAMS
8 00-12 00 *Orthopedic Surgery* Operative Clinic
On lay Bone Graft DALLAS B PEMISTER
8 00-12 00 *Genitourinary Surgery* Operative and Nonoperative Clinics
Nephrectomy Cystectomy CHARLES B HUGGINS
2 00-5 00 *Otolaryngology* Operative Clinics
Fenestration JOHN R LINDSAY
Radical Mastoidectomy HENRY B PERLMAN

Thursday

8 00-12 00 *General Surgery* Operative Clinics
Vagotomy LESTER R DRAGSTEDT
Carcinoma of Bowel J GARROTT ALLEN
8 00-12 00 *General Surgery* Operative and Nonoperative Clinics
Carcinoma of Thyroid DWIGHT E CLARK

8 00-12 00 *Orthopedic Surgery* Operative Clinic
Local Resection of Tumor of the Bone C HOWARD HATCHER

2 00-5 00 *Otolaryngology* Operative Clinics
Rhinoplasty HEINRICH G KOBRACK
Palataryngectomy HAROLD F SCHUCKNECHT

CHICAGO LYING IN HOSPITAL

Monday

2 00-4 30 *Obstetrics and Gynecology* Nonoperative Clinics
Cancer HERBERT P FRIEDMAN
Cardiac Disease MARY LOU LILBERT
Ovarian Function M EDWARD DAVIS
Cesarean Section WILLIAM J DIECKMANN
Cancer Test SAMUEL LIPTON
Vulva H CLOSE HESSELTINE
Nutrition in Pregnancy DR MEILLER.
Erythroblastosis EDITH L POTTER.

Tuesday

9 00-12 30 *Obstetrics and Gynecology* Operative Clinics
Cesarean Section Gynecologic Operations WILLIAM J DIECKMANN
2 00-4 30 *Obstetrics and Gynecology* Nonoperative Clinics
Newborn Pediatrics W HEPNER
Maternal and Fetal Mortality WILLIAM J DIECKMANN
Infection H CLOSE HESSELTINE
Menses and Weight Change MRS L RYNKIEWICZ
Cancer Test. LESTER D ODELL.
Tuberculosis R H EBERT
Gastrointestinal J B KIRSNER
Bacteremia E C TURNER
Premature Mortality EDITH L POTTER

Wednesday

9 00-12 30 *Obstetrics and Gynecology* Operative Clinics
Cesarean Section and Gynecologic Operations H CLOSE HESSELTINE
2 00-4 30 *Obstetrics and Gynecology* Nonoperative Clinics
Spinal Anesthesia H PRIDDLE
Chemistry Aids MR R L POTTINGER
Newborn Pediatrics H WRIGHT
Preeclampsia WILLIAM J DIECKMANN
Delivery Weight Lost C P MCCARTNEY
Abortion M EDWARD DAVIS
Placental Removal LESTER D ODELL.
Liver Function R SMITTFR

Thursday

9 00-12 30 *Obstetrics and Gynecology* Operative Clinics
Cesarean Section and Gynecologic Operations M EDWARD DAVIS
2 00-4 30 *Obstetrics and Gynecology* Nonoperative Clinics
Endocrine N FUGO
Newborn Pediatrics D CASSFELS
Vulvar Fluorescence M EDWARD DAVIS
Diabetes Mellitus H RICKETTS
Congenital Syphilis EDITH L POTTER
Infection H CLOSE HESSELTINE
Enzymes LESTER D ODELL.
Mastitis H PRIDDLE

CHILDREN'S MEMORIAL HOSPITAL

Monday

2:00-4:00 *Orthopedic Surgery* Nonoperative Clinic
General Orthopedic Clinic CHARLES N PEASE

Tuesday

8:00-10:00 *Orthopedic Surgery* Operative Clinics
Abdominal Extraperitoneal Section of Obturator Nerve
Panarthrodesis of Foot. Transplant of Tendons of
Toe Extensors Into Heads of Metatarsals CHARLES N
PEASE

Wednesday

9:00-11:00 *General Surgery* Operative Clinic
Repair of Inguinal Hernia in Infants, 2 cases PAUL F
FOX
Surgical Division of Patent Ductus Arteriosus WILLIS
J PORTS

Rhinoplasty SAMUEL SALINGER, BERNARD M. COHEN

Friday

- 8 00-12 00 *General Surgery* Operative Clinics
Diaphragmatic Hernia RALPH B. BITTMAN
Selected Cases NATHAN N. CROHN, MILTON W. FISENSTEIN, RICHARD M. BENDIN, GERALD J. MENAKER, CHARLES A. SCHIFF
8 00-12 00 *Orthopedic Surgery* Operative Clinics
Selected Cases JEROME G. FINDER, HARRY R. BARRETT, LEONARD WEINSTEIN
10 00-12 00 *Gynecology* Operative Clinics
Cesarean Section HENRY BUNBAUM

MOUNT SINAI HOSPITAL

Monday

- 8 00-12 00 *Orthopedic Surgery* Operative Clinics
Orthopedic Surgical Clinic LEO F. MILLER
Drop Graft for Non Union of Tibia DONALD MILLER
8 00-12 00 *Obstetrics* Operative Clinics
Cesarean Section S. J. BENENSON
Porro Cesarean Section CHARLES FIELDS
10 00-12 00 *Gynecology* Operative Clinic
Vaginal Hysterectomy HAROLD BRILL

Tuesday

- 8 00-12 00 *General Surgery* Operative Clinic Congenital
Heart Case J. GERT H. FELL, BENJAMIN M. GASUL
8 00-12 00 *Gynecology* Operative Clinic Vaginal Hysterectomies for Pelvic Herniosis A. F. LASH

Wednesday

- 8 00-12 00 *Gynecology* Operative Clinic Vaginal Hysterectomies and Vaginal Plastics AARON E. KANTER
8 00-12 00 *General Surgery* Operative Clinic Gastric Resections ALFRED A. STRAUSS, SIEGFRIED F. TRAUSS

Thursday

- 8 00-12 00 *General Surgery* Operative Clinics
Resection of Colon LARLE I. GREFNE
Thyroidectomy JOSEPH T. GAULT
Common Bile Duct Reconstruction LEON J. ARIES
Sphenous Vein Ligations L. WILLARD SHABAT
Removal of Foreign Bodies (Needles from Hand and Foot) Demonstration of Electrical Forceps and New Screen Localizer DAVID A. WILLIS
1 00-4 00 *Neurosurgery* Operative Clinic Neuro-Surgical Cases MILTON TINSLEY

Friday

- 8 00-12 00 *Urology* Operative Clinics
Retropubic Prostatectomy HARRY C. ROLNICK
Transurethral Prostatectomy LEO A. MASLOW
11 00-12 00 *Pathology* Nonoperative Clinic Clinical Pathological Conference I. DAVIDSON

PASSAVANT MEMORIAL HOSPITAL

Monday

- 8 00-11 00 *Neurosurgery* Operative Clinic LOYAL DAVIS

- 8 00-11 00 *Gynecology* Operative Clinic JOHN I. BREWER
8 00-11 00 *Urology* Operative Clinic LEANDER W. RIBA
8 00-12 00 *General Surgery* Operative Clinic SUMNER L. KOCH, MICHAEL L. MASON, HARVEY S. ALLEN
8 00-12 00 *Ophthalmology* Operative Clinic DERRICK T. VAIL, IRVING PUNTENFELT
1 00-4 00 *Orthopedic Surgery* Operative Clinic JAMES K. STACK, WILLIAM A. LARMON

Tuesday

- 8 00-11 00 *General Surgery* Operative Clinics JOHN A. WOLFFER, THOMAS C. DOUGLASS, and WALTER W. CARROLL
8 00-11 00 *Urology* Operative Clinic KNOWLTON I. BARBER
8 00-12 00 *Gynecology* Operative Clinic JOHN W. HUFFMAN
1 00-4 00 *General Surgery* Operative Clinic BENJAMIN F. LOUNSBURY
1 00-4 00 *Urology* Operative Clinic FREDERICK A. LLOYD
1 00-4 00 *Gynecology* Operative Clinic STUART ABEL
3 00-5 00 *Orthopedic Surgery* Nonoperative Clinic EMIL D. W. HAUSER

Wednesday

- 8 00-11 00 *Neurosurgery* Operative Clinic LOYAL DAVIS
8 00-11 00 *Gynecology* Operative Clinic JOHN I. BREWER
8 00-11 00 *Urology* Operative Clinic LEANDER W. RIBA
8 00-12 00 *General Surgery* Operative Clinic SUMNER L. KOCH, MICHAEL L. MASON, HARVEY S. ALLEN
8 00-12 00 *Ophthalmology* Operative Clinic DERRICK T. VAIL, IRVING PUNTENFELT
1 00-4 00 *Orthopedic Surgery* Operative Clinic JAMES K. STACK, WILLIAM A. LARMON
1 00-5 00 *Thoracic Surgery* Operative Clinic GEORGE W. HOLMES

Thursday

- 8 00-11 00 *General Surgery* Operative Clinics JOHN A. WOLFFER, THOMAS C. DOUGLASS, WALTER W. CARROLL
8 00-11 00 *Urology* Operative Clinic KNOWLTON I. BARBER
8 00-12 00 *Gynecology* Operative Clinic JOHN W. HUFFMAN
1 00-4 00 *General Surgery* Operative Clinic BENJAMIN F. LOUNSBURY
1 00-4 00 *Urology* Operative Clinic FREDERICK A. LLOYD
1 00-4 00 *Gynecology* Operative Clinic STUART ABEL
3 00-5 00 *Orthopedic Surgery* Nonoperative Clinic EMIL D. W. HAUSER

Friday

- 8 00-11 00 *Neurosurgery* Operative Clinic LOYAL DAVIS
8 00-11 00 *Gynecology* Operative Clinic JOHN I. BREWER
8 00-11 00 *Urology* Operative Clinic LEANDER W. RIBA

THE CLINICAL CONGRESS TECHNICAL EXHIBITION

THE Clinical Congress Technical Exhibition provides an attractive method of displaying supplies and equipment designed for use in hospitals and surgeons' offices, such as surgical instruments, diagnostic and therapeutic apparatus, pharmaceuticals, medical literature, and other similar items. The 1949 Technical Exhibition will be located in the Exposition Hall of The Stevens James S Shannon, General Manager of The Franklin H Martin Memorial Foundation, publishers of the Official College Journal, SURGERY, GYNECOLOGY AND OBSTETRICS, is Manager of the Technical Exhibition. The list of exhibitors follows:

Abbott Laboratories, North Chicago
 Acme Engineering Co, Inc., Greensboro, N C
 W D Allison Company, Indianapolis
 A S Aloe Company, St Louis
 American Cystoscope Makers, Inc, N Y
 American Hospital Supply Corp, Evanston, Ill
 American Safety Razor Corporation, Brooklyn
 American Sterilizer Company, Erie, Pa
 Ames Company, Inc, Elkhart, Ind
 Appleton Century-Crofts, Inc, N Y
 The Armour Laboratories, Chicago
 The Gordon Armstrong Company, Inc, Cleveland
 Associated Medical Care Plans, Chicago
 Austenal Laboratories, Inc, N Y
 C R. Bard, Inc, Summit, N J
 Bard Parker Company, Inc, Danbury, Conn
 Bauer & Black, Chicago
 W A Baum Company, Inc, N Y
 Rudolph Beaver, Waltham, Mass
 Becton, Dickinson & Company, Rutherford, N J
 Brol Instruments, Inc, N Y
 Burdick Corporation, Milton, Wis
 Burroughs Wellcome & Co (USA) Inc, Tuckahoe, N Y
 Cameron Surgical Specialty Company, Chicago

THIRTEENTH CONGRESS, INTERNATIONAL SOCIETY OF SURGERY

(Société Internationale de Chirurgie)

New Orleans, Louisiana, U S A , October 9 to 15, 1949

THE following announcement has been received from Dr L Dejardin, Secretary-General of the International Society of Surgery

Plans for the Thirteenth Congress of the International Society of Surgery, which will take place in New Orleans, Louisiana, under the Presidency of Professor George Grey Turner, of London, England, are now in course of preparation

The scientific program was settled by the General Assembly at the last Congress in London, held in September, 1947 This body, at the recommendation of the Scientific Committee, also accepted two additional subjects, and decided who should open each discussion The final arrangements were as follows

- 1 Surgery and Pathology of the Pancreas, Especially in Relation to Its Endocrine Function Opened by PROFESSOR IAN AIRD, London
- 2 Surgery of the Parathyroid Glands Opened by DR PAOLUCCI, Rome
- 3 Surgery of the Suprarenal Glands Opened by DR. M R FONTAINE, Strasburg
- 4 Pathology and Surgery of the Pituitary Glands Opened by DR M P MARTIN, Brussels
- 5 Treatment of Postoperative Thrombosis and Its Sequelae Opened by DR ALTON OCHSNER, New Orleans, and DR. MICHAEL DE BAKEY, Houston
- 6 Causes of Recurrence after Operations on the Biliary Tract Opened by DR. M R DEMEL, Vienna

In addition, the American Organizing Committee has arranged that two days of the meeting shall be devoted to the presentation of shorter papers on subjects of immediate interest

The program as formulated by Vice President Evarts A Graham, of St Louis, Missouri, is as follows

Friday, October 14

- 9 00 a m The Treatment of Radiation Burns J BARRETT BROWN, M D , St Louis, Missouri, Washington University School of Medicine
- 9 20 Chloromycetin in Gas Gangrene WILLIAM A ALTEMEIER, M D , Cincinnati, Ohio, University of Cincinnati College of Medicine
- 9 35 An Evaluation of Aureomycin and Chloromycetin (Chloramphenicol) in Experimental Clostridium Welchii Infection WILLIAM R SANDUSKY, M D , Charlottesville, Virginia, University of Virginia Medical School

- 9 50 The Use of Pancreatin in the Reduction of the Increased Fecal Nitrogen and Fecal Fat Loss Occurring after Total Gastrectomy TILDEN C EVERSON, M D , MORTON I GROSSMAN, M D , and ANDREW C IVY, M D , Chicago, Illinois, University of Illinois College of Medicine
- 10 05 Potassium Deficiency and Alkalosis in the Surgical Patient EVERETT I EVANS, M D , Richmond, Virginia, Medical College of Virginia
- 10 20 The Use of Hypertonic Sodium Chloride in Experimental Dehydration RICHARD A LEMMER, M D , and ROBERT ELMAN, M D , St Louis, Missouri, Washington University School of Medicine
- 10 35 The Comparative Effects of Various Electrolytic and Nonelectrolytic Hypertonic Solutions upon the Volume of the Brain and Intracranial Pressure BEN WILSON, M D , Dallas, Texas, Southwestern Medical College
- 10 50 Recent Developments on the Temporary Maintenance of Life with an Extracorporeal Circulation JOHN H GIBBON, JR , M D , and THOMAS LANE STOKES, M D , Philadelphia, Pennsylvania, Jefferson Medical College
- 11 05 a m Prolonged Occlusion of the Venae Cavae with Survival by means of an Extracardiac Shunt SANFORD LEEDS, M D , NORMAN GRAY, M D , ORRIN S COOK, M D , and H GLENN BELL, M D , San Francisco, California, University of California Medical School
- 11 20 Cardiovascular Dynamics in Patients with Coarctation of the Aorta, Studied Before, During and After Surgical Treatment of the Disease GEORGE A HALLENBECK, M D , EARL H WOOD, M D , and O THERON CLAGETT, M D , Rochester, Minnesota, Mayo Clinic
- 11 35 Experimental Production and Closure of Cardiac Interventricular Septum Defects HOWARD C NAFFZIGER, M D , MAURICE GALANTE, M D , ROBERT JOHANSEN, M D , RICHARD GARDNER, M D , H BRODIE STEPHENS, M D , and H J MCCORKLE, M D , San Francisco, California, University of California Medical School
- 11 50 A New Suture Technique of Blood Vessels EDGAR J POTH, M D , Galveston, Texas, University of Texas School of Medicine

Afternoon Session

- 2 00 p m The Roentgen Anatomy of the Femoral Vein after Surgical Interruption D EMERICK SZILAGYI, M D , Detroit, Michigan, Henry Ford Hospital
- 2 15 Newer Concepts of Blood Coagulation JOHN KAY, M D , New Orleans, Louisiana, Tulane University School of Medicine

- 2 30 Studies in Cardiac Resuscitation. CHARLES K KIRBY, M D, and JULIAN JOHNSON, M D, Philadelphia, Pennsylvania, University of Pennsylvania Medical School
- 2 45 The Venous Circulation in Experimental Hemorrhagic Shock E FRIEDMAN, M D, H A FRANK, M D, and J FINE, M D, Boston, Massachusetts, Harvard Medical School
- 3 00 Gastric Vagotomy in Peptic Ulcer LESTER R DRAGSTEDT, M D, Chicago, Illinois, University of Chicago Medical School
- 3 15 p m Effects of Vagus Nerve Resection with Subtotal Gastrectomy upon the Development of the Mann Williamson Ulcer JAMES OLIVER, M D, Chicago, Illinois, University of Illinois Medical School
- 3 30 A Study of the Extrinsic Nerve Supply Regulating Gastrointestinal Activity ROBERT M WHITROCK, M D, and HENRY L TICHE, M D, Ann Arbor, Michigan, University of Michigan Medical School
- 3 45 Role of Autonomic Nervous System in Gastric Secretion C FREDERICK KITTLE, M D, Kansas City, Kansas, University of Kansas Medical School
- 4 00 The Effect of Splanchnicectomy and Vagotomy on Pancreatic Function with Special Reference to a New Technic for Obtaining Pancreatic Secretion HUSHANG JAVID, M D, Chicago, Illinois, University of Illinois Medical School
- 4 15 The Utilization of Intravenously Injected Human Serum Albumin NICHOLAS S GIMBEL and CECILIA RIEGEL, Philadelphia, Pennsylvania, University of Pennsylvania School of Medicine
- 4 30 Studies in Experimental Frostbite JOSEPH C FINNERAN, M D, and HARRIS B SHUMACKER, JR., M D, Indianapolis, Indiana, University of Indiana Medical School
- 4 45 Treatment of Fibrocystic Disease of the Pancreas and Associated Bronchial Lesions by Splanchnicectomy WILLIAM AYERS, M D, New Orleans, Louisiana, Tulane University Medical School

Saturday, October 15

- 9 00 a m Controlled Respiration in Thoracic Surgery JOHN H GIBBON, JR., M D, JOSEPH W STAYMAN, JR., M D, and FRANK F ALLBRITTEN, JR., M D, Philadelphia, Pennsylvania, Jefferson Medical College
- 9 15 The Eck Fistula An Experimental Study ALFRED M LARGE, M D, and D E PRESHAW, M D, Detroit, Michigan, Wayne University College of Medicine
- 9 30 The Effect of Arteriovenous Fistula on Bone Growth, An Experimental Study J M JAMES, M D, and J E MUSGROVE, M D, Rochester, Minnesota, Mayo Clinic
- 9 45 The Use of Arteriovenous Shunts in Ischemic Limbs PRESCOTT JORDAN, M D, and CHARLES G JOHNSTON, M D, Detroit, Michigan, Wayne University College of Medicine
- 10 00 Application of Surgical Therapy to Extrapyloric Diseases RUSSELL MEYERS, M D, Iowa City, Iowa, University of Iowa Medical School
- 10 15 Lumbar Ganglionectomy in Peripheral Arteriosclerosis LEON GERBER, M D, Washington, D C, George Washington University

- 10 30 The Use of Nor-Epinephrine as a Pressor Drug with Special Reference to Thoracolumbar Sympathectomy R A DETERLING, M D, VIRGINIA APGAR, M D, and MARCEL GOLDENBERG, M D, New York, Columbia University College of Physicians and Surgeons
- 10 45 A Fluorimetric Method of Blood Adrenalin Determination WILLIAM W SHINGLETON, M D, and HORACE M BAKER, M D, Durham, North Carolina, Duke University School of Medicine
- 11 00 The Evaluation of Pulmonary Function in Surgical Patients JULIUS H COMROE, JR., M D, and WILLIAM S BLAKEMORE, M D, Philadelphia, Pennsylvania, University of Pennsylvania Medical School
- 11 15 a m The Effects of Curare and Pentothal Anesthesia upon Respiratory Control Mechanisms MARION P JENKINS, M D, Dallas, Texas, Southwestern Medical College
- 11 30 The Pathogenesis of Hyperthyroidism PETER HEINBECKER, M D, St. Louis, Missouri, Washington University School of Medicine
- 11 45 Studies of the Oxygen Consumption of Liver Biopsies LAWRENCE O ELY, M D, Iowa City, Iowa, University of Iowa Medical School

Afternoon Session

- 2 00 p m Studies in Experimental Alkalosis ROBERT E L BERRY, M D, VIVIAN IOB, M D, DANIEL C THOMPSON, M D, RALPH D MAHON, M D, and SAM J GREER, M D, Ann Arbor, Michigan, University of Michigan Medical School
- 2 15 p m Liver Regeneration in Animals and Man HARRY M VARS, M D, and I S RAVDIN, M D, Philadelphia, Pennsylvania, University of Pennsylvania Medical School
- 2 30 The Fate of Transfused Blood as Determined by Red Cells Tagged with P_{32} and Albumin Tagged with Iodine 131 JOE MABEY, M D, New Orleans, Louisiana, Tulane University Medical School
- 2 45 Aortic Anastomosis in Pups Studied after Reaching Adulthood JAMES BROOKS, M D, Richmond, Virginia, Medical College of Virginia
- 3 00 Internal Jugular Phlebectasia. WALTER H GERWIG, M D, Washington, D C, George Washington University Medical School
- 3 15 Subtotal Gastrectomy with Gastrooduodenostomy LAURENCE S FALLIS, M D, Detroit, Michigan, Henry Ford Hospital

OFFICERS FOR THE BIENNium

- GEORGE GREY TURNER, London, England, *President*
 GORDON GORDON TAYLOR, London, England, *Vice-President*
 P MATHIEU, Paris, France, *Vice President*
 R DOS SANTOS, Lisbon, Spain, *Vice President*
 EVARTS A GRAHAM, St. Louis, Missouri, U S A, *Vice-President*
 SERGEI S YUDIN, Moscow, U S S R, *Vice-President*
 J VERHOOGEN, Brussels, Belgium, *President of International Committee*
 LEO A M DEJARDIN, Brussels, Belgium, *Secretary-General*
 PAUL E LORTHOIR, Brussels, Belgium, *Treasurer*
 G SPEHL, Brussels, Belgium, *Editor, "Journal International de Chirurgie"*
 I MINIS GAGE, New Orleans, Louisiana, *Secretary of the 13th Congress*

NATIONAL COMMITTEE FOR THE UNITED STATES

RUDOLPH MATAS, New Orleans, Louisiana, *Honorary
Chairman*

ARTHUR W ALLEN, Boston, Massachusetts, *Chairman*

ALFRED BLALOCK, Baltimore, Maryland, *Vice Chairman*

W BARCLAY PARSONS, New York, New York, *Secretary*

FREDERIC W BANCROFT, New York, New York, *Treasurer*

HARRY H. KERR, Washington, District of Columbia, *Recorder*

ADVISORY COMMITTEE FOR THE UNITED STATES

CHARLES G MIXTER, Boston, Massachusetts

ALLEN O WHIPPLE, New York, New York

HARVEY B STONE, Baltimore, Maryland

I S RADVIN, Philadelphia, Pennsylvania

DALLAS B PREMISTER, Chicago, Illinois

EVARTS A GRAHAM, St Louis, Missouri

FREDERICK A COLLIER, Ann Arbor, Michigan

ALFRED W ADSON, Rochester, Minnesota

HOWARD C NAFFZIGER, San Francisco, California

IRVIN ABELL, Louisville, Kentucky *

DANIEL C. ELKIN, Atlanta, Georgia

ALTON OCHSNER, New Orleans, Louisiana

Inquiries should be directed to

Dr L DEJARDIN, *Secretary-General*

International Society of Surgery

141, Rue Belliard, Brussels, Belgium

COLLECTIVE REVIEW

EVALUATION OF THE PRINCIPLES CONCERNED IN THE MANAGEMENT OF TRAUMA TO THE KIDNEY

LAZARUS A ORKIN, M D, F A C S, New York, New York

A REVIEW of the voluminous literature on trauma to the kidney is quite disconcerting. There is a marked divergence of opinion regarding several important problems concerned in the management of renal injuries.

These problems are

1 The proper method of examining patients who have sustained a renal injury—whether by means of excretory or retrograde pyelography, or both

2 Whether to practice systematic surgical intervention or conservative expectant treatment

3 The indications for surgical intervention and the time for such interference

4 Whether to repair the kidney or remove it

5 The late results that may be expected following the various types of immediate treatment

In order to answer these problems, I have undertaken a collective study of the literature and have reviewed our 27 cases of renal injury at Beekman-Downtown Hospital.

ANALYSIS OF 27 CASES AT BEEKMAN- DOWNTOWN HOSPITAL, (1940-1948)

ETIOLOGY

The oldest patient in this series was 76 years of age and the youngest was 17 years. The average age was 44.6 years. All of the patients were

From the Surgical and Genitourinary Services of Beekman Downtown Hospital.

Presented in part in the symposium on Fractures and Other Traumas before the Clinical Congress of the American College of Surgeons, Los Angeles, October 19, 1948.

males. In 16 cases the right side was involved and in 11, the left side.

Nature of the injuries. The injuries to the kidney were often variable and disproportionate to the violence to which the patient had been subjected. They were due to

1 Direct force—such as sudden severe external trauma to the loin, over the kidney, falls striking the back or abdomen, and crushing force as when run down by automobile (14 cases)

2 Indirect force—such as falls with the body landing upon the head, feet, buttocks, without direct trauma over the kidney area (9 cases)

3 Kicks or blows over the kidney—the patients attributed their injuries of the kidney to probable blows sustained while playing football (2 cases)

4 Penetrating or puncture wounds—there was 1 gunshot wound

5 No demonstrable cause or history of injury—there was 1 case of spontaneous perforation of the ureter

PATHOLOGY

In this series, there were 11 cases of contusion, 14 of rupture, 1 case of traumatic hydrocele of the kidney, and 1 of spontaneous perforation of the ureter. The severity of the injury did not depend, as a rule, on the trauma producing it, nor upon the manner in which it was applied.

SYMPTOMS

The symptoms were variable and inconstant.

1 Shock was present in 14 cases and absent in 13 cases. In 6 it was quite severe on admission,

and 3 of the patients in the last group never completely recovered from their shocked condition

2 Pain was present in 21 cases. It was limited to the loin on the injured side in 10 cases, to the loin and abdomen on the injured side in 13, and to the loin, abdomen, and chest in 4

3 Tenderness was present in the costolumbar region in all but 1 of these cases

4 Muscular rigidity was present in the loin of the injured side in 23 cases, over the corresponding side of the abdomen in 11, and generalized over the abdomen in 5

5 Hematuria was present in 26 cases and absent in 1 case. It was microscopic in 9, and gross in 17. Six of the patients could not void after admission, and had to be catheterized, at which time gross hematuria was discovered. There were 2 instances of severe secondary bleeding in patients allowed out of bed too soon, and 2 cases in which the bleeding persisted and was profuse in nature. There was no correlation between the severity of the injury and the amount of hematuria, as in many of these cases the injury appeared to be trivial and the hematuria profuse

6 A large retroperitoneal mass could be felt in 9 cases, and, although present, was missed in 2 other instances

7 Abdominal distention was noted in 19 cases, and abdominal rigidity in 4. Pain in the lower quadrant on the side corresponding to the injury in association with psoas spasm was found in 3 instances

8 Anuria lasting from 24 to 36 hours was seen in 2 patients who were not in shock. This was believed to be due to suppression on the injured side and reflex urinary suppression of the contralateral kidney

9 Severe bruises, discolorations, and ecchymosis in the affected loin were present in 12 cases and absent in 15

10 A severe secondary anemia out of all proportion to the amount of hematuria was noted in 6 cases

A review of the symptoms disclosed that there was no apparent relationship between their severity and the actual injury sustained by the kidney. The symptoms were variable, inconstant, and confusing and did not justify more than a presumptive diagnosis. In 2 of the cases, the symptoms and signs were entirely those of a ruptured intra-abdominal viscus, the injury to the kidney only being realized at a later date

DIAGNOSIS

The following diagnostic measures were used in this series

1 A simple abdominal film was taken in 19 cases. It gave only suggestive evidence of kidney injury in 4 cases, and was entirely misleading in 1 case. In the latter, the radiologist reported free air under the diaphragm which was not confirmed by exploratory laparotomy. The simple abdominal film was of value in determining associated lesions in 13 cases in which fracture of the transverse processes of the vertebrae, fracture of the pelvis, or of the lower ribs were diagnosed

2 Excretory urography was done soon after admission in 20 cases. Satisfactory pyelograms for diagnostic purposes were obtained in 6. In 2 cases extravasation was suspected on the excretory study, but on retrograde study only one of these could be confirmed. In 2 other cases, although the intravenous pyelograms showed that the kidney had sustained an injury, there was no demonstrable evidence of extravasation. At operation, both of these kidneys were found to be badly ruptured. Valuable information concerning the uninjured kidney was obtained in 16 of the cases

3 Cystoscopy and retrograde pyelography were done in 9 cases. Extravasation was suspected on the intravenous pyelogram in 2 cases, it was confirmed by the retrograde pyelogram in one instance, and disproved in the other, in 3 cases, although the excretory study was interpreted as normal, the retrograde study demonstrated extravasation. In 2 cases, the excretion on the injured side was indefinite but the retrograde study showed intraparenchymal rupture. In 1 case, there was no excretion visualized on the intravenous pyelogram but the pyelogram was normal by retrograde study. In another instance, observation cystoscopy disclosed a bleeding carcinoma of the bladder as the cause of the hematuria

ASSOCIATED COMPLICATIONS

Serious complications were present in 19 cases, and absent in 8. Their prevalence and wide distribution in this and other such series stresses the absolute need of a complete physical examination. The kinds of complicating injuries in this series were as follows

A Fractures

- Skull—2
- Bones of face—2
- Lumbar vertebrae—5
- Sacrum—1
- Bony pelvis—2
- Wrist—1
- Clavicle—1
- Ankle—1
- Radius—1

- B Dislocations
 - Ankle—1
 - Separation of symphysis—1
- C Injury to viscera
 - Rupture of liver—3
 - Rupture of spleen—2
 - Rupture of bladder—1
 - Rupture of spleen—1
- D Other complicating injuries
 - Pneumothorax—1
 - Shift of mediastinum—1
 - Hemothorax—2
 - Perforation of diaphragm—1
 - Laceration of brain—1
 - Laceration of facial nerve—1
 - Gas bacillus infection of leg—1
 - Rupture of lung—1
- E Other complicating conditions
 - Carcinoma of bladder—1
 - Malaria—1

Three-quarters of the deaths in this series of cases were a result of the complicating injuries, and not the result of injury to the kidney which in these instances was trivial in nature

TREATMENT

Expectant treatment Twenty-two patients were treated conservatively. In 11 the injury was diagnosed as contusion, in 2, a laceration, and in 9, a rupture of the kidney. Four of these patients had to be operated upon, 2 because of the recurrence of profuse hematuria, 1 because of the development of an infected hydrocele of the kidney, and 1 because of sepsis due to a large perinephritic abscess as a result of extravasation. There were 2 deaths among the conservatively treated patients, a mortality of 12.5 per cent.

Conservative surgery This was done in 4 cases. One patient had a decapsulation of the kidney and pyelostomy for an infected hydrocele of the kidney, 1 with spontaneous perforation of the ureter had an incision and drainage of the loin and pyelotomy, and 2 patients had an exploratory laparotomy, 1 of them because of a mistaken diagnosis of ruptured viscus, and 1 because of peritonitis due to a ruptured bladder, liver, and spleen. There was 1 death, a mortality of 25 per cent.

Radical surgery Nephrectomy was done in 5 cases. Three of the patients were treated conservatively at first. In 1, because of profuse and persistent secondary hemorrhage, the kidney was explored, and was found to be ruptured although the excretory pyelograms showed no evidence of extravasation. In another patient treated conservatively the excretory pyelograms showed a dilated pelvis and ureter filled with blood clots

but no evidence of extravasation. This patient had persistent gross hematuria for 2 weeks and was finally explored. A ruptured kidney was found and removed. The third patient who was treated conservatively ceased bleeding but developed severe loin pain with evidence of sepsis. Retrograde study revealed extravasation into a large abscess cavity. Nephrectomy was performed. One patient had a rupture of the kidney, liver, and lung due to a bullet, nephrectomy was the procedure of choice because of the severe bleeding. In the fifth case, the patient was explored abdominally because of signs pointing to a ruptured intra-abdominal viscus. The abdominal findings were negative but transabdominal nephrectomy was done for a pulpified kidney. There was 1 death in this group, a mortality of 20 per cent.

RESULTS

Deaths There was a total of 4 deaths in this series of 27 cases, a mortality of 14.8 per cent. In 1 case only should the cause of death be attributed to the kidney (4.1%).

Cause of death—rupture of kidney 1. A patient with persistent bleeding in whom the excretion showed no evidence of extravasation was finally subjected to operation because of a constant decline in the clinical picture due to hemorrhage. (At operation the kidney was found to be badly ruptured.) This patient should have been operated upon earlier and I was entirely misled by the normal intravenous pyelograms.

Cause of death—severe associated injuries

1. In the first patient there was a contusion of the kidney with hematuria which ceased soon after admission, but the patient died in 48 hours from a ruptured lung, pneumothorax, and mediastinal shift.

2. In the second patient there was also a contused kidney with a ruptured bladder, liver, and spleen, and a fracture of the tibia and fibula. The patient died soon after abdominal exploration and drainage, but at autopsy the kidney was found not to be severely injured.

3. In the third patient there was a ruptured kidney and spleen with compound fracture of the leg and gas bacillus infection of the extremity. Because the patient never came out of shock, he was treated conservatively. At autopsy, the kidney was not severely ruptured.

Late results A follow up is available in 23 cases. In the 10 cases of contusion of the kidney, the end result is good, pyelographically and functionally. Four patients who had a nephrectomy are well and symptom-free. The 3 patients on whom

ORKIN MANAGEMENT OF TRAUMA TO THE KIDNEY

317

injury Pyelograms taken at a later date reveal either normal or relatively normal excretion, or complete or partial inability to excrete the contrast substance due to replacement of the parenchyma by scar tissue (36, 102, 103, 104, 105, 142, 149)

6 Researches in dogs on the vasoconstrictor reactions to contusion of the kidney reveal that after trauma the blood pressure is 150 mm Hg in all, as compared to 119 mm Hg before the contusion (148, 149)

7 In accordance with the classification outlined before, recovery is uneventful following Type 1 injury, while following Type 2 injuries, healing is slower, but recovery is also uneventful About 80 per cent of the animals died at varying times after Type 3 injuries, although all of the animals with this type of injury who had operative repair survived All animals with Type 4 injuries died (142, 145)

8 Experimentally untreated Type 3 traumatized kidneys in the animals that lived often gave rise to marked loss of function in the injured organ, and occasionally produced complications of such magnitude that some form of surgical intervention became necessary later (22, 109, 127, 141, 142)

9 Fat is an excellent hemostatic agent, and has been found to control bleeding in from $\frac{3}{4}$ to $1\frac{1}{2}$ minutes while muscle does so in from 16 to 20 minutes The efficacy of ribbon gut has also been demonstrated by Lowsley In no case following experimental surgical repair was the kidney destroyed Microscopically, actively functioning tubules and glomeruli are found at the edge of the reparative scar tissue in these surgically repaired kidneys (64, 75)

10 Fibrin foam, gelfoam, and oxycellulose gauze used in the control of bleeding kidney wounds produces a narrow scar with little or no sclerosis of the surrounding renal parenchyma (54, 74, 75, 76, 77)

11 Following severe injuries to the kidney, there may be a marked secondary anemia, persistent and unrelated to the hemorrhage Reticulocyte counts suggest that this phenomena is due to toxemia from the degenerated and necrotic kidney tissue Simultaneous depression of hemopoiesis by the toxic agent is not ruled out, however (140)

SYMPTOMS AND SIGNS

A review of the symptoms and signs of renal injuries in reported cases and in our series impresses one with the fact that there is a wide diversity of the clinical picture presented

There are no pathognomonic symptoms since any or all of the so-called classical symptoms of pain, hematuria, and shock may be absent I wish to discuss briefly the symptoms that may be encountered in renal trauma, and to point out their implications

Shock If present, shock is usually slight at the outset and is proportional to the character and magnitude of the external force rather than to the extent of the actual kidney injury Wesson (156) has pointed out that shock at the time of the trauma is usually due to injury of the solar plexus, whereas, if it occurs after a lapse of several hours, it is due to hemorrhage If the degree of shock which has been present at the outset does not disappear in a relatively short time but shows a tendency to become aggravated, or if it continues to be severe, one should consider the possibility of an associated injury of the abdominal viscera, the thorax or spinal cord, or of an exacerbation of bleeding from the kidney itself

Hematuria Microscopic or gross hematuria is a cardinal sign of renal injury, and occurs in from 75 to 90 per cent of the cases It was found in 26 of the 27 cases in our series (96%) Hematuria may not appear for hours or days after the accident Occasionally, it may be absent entirely if the injury is slight, if blood clots are blocking the ureter, if the ureter has been completely severed, if the pelvis or calyces are blocking the line does not enter the pelvis or calyces For all of these reasons, there is no correlation between the presence or absence, or the amount and duration, of hematuria with the existence or degree of the renal injury As a general rule, however, the more profuse the hematuria, the more extensive the injury

There is a tendency for the hematuria to cease by the fourth or fifth day unless the injury has been extensive, or unless secondary bleeding occurs The latter is usually noted in the second or third week after the injury, and has been reported as late as 2 months, it differs from the primary bleeding in that it is more severe and persistent, and frequently gives rise to blood clots (40) Two of our patients had marked secondary bleeding on being allowed out of bed too soon, and on 1 of these, immediate nephrectomy had to be performed because of the alarming and persistent hemorrhage

Bailey has estimated that in 8 per cent of cases, acute retention ensues because of clots in the bladder (6)

Mass in loin A mass in the loin on the outside, found in 25 per cent of the complicated cases, is a feature of ruptured kidney It was present

11 (43%) of the cases in our series. The mass may be of variable size, and slow to rapid in its development, it is usually noted soon after the injury. As a rule, its size is an index of the degree of severity of the injury, and its palpation and delineation may be very difficult because of the accompanying loin rigidity and tenderness, and abdominal distention. Occasionally, the presence of a retroperitoneal mass or hemorrhage may be missed or overshadowed by the presence of the signs of peritonitis. Backus has reported 7 such cases, in 6 of which the patient was subjected to exploratory laparotomy with negative abdominal findings (5).

The mass may be absorbed, and the time required for such absorption is directly proportional to the initial size of the mass. Infrequently, it may become encysted and calcified, and form a large calcified cyst as reported by Goldstein (164, 165). Occasionally, it becomes infected and produces a perirenal cellulitis or abscess and, secondarily, cortical abscesses of the kidney. In 2 of our cases, it persisted to form a large cyst of the lower pole, and in 1 case degeneration occurred to form a large perirenal abscess.

Pain and tenderness in the affected costolumbar region and/or the upper quadrant anteriorly are usually present and were found in more than 85 per cent of our patients. They are directly proportional to the severity of the injury, but seem to bear no relation to the extent of the kidney damage produced. They may be due to trauma of the abdominal wall, fracture of the lower ribs, contusion of the soft parts, pull on the pedicle, and occasionally to clots in the ureter. An interesting finding which has often been noted but not stressed sufficiently is that outlined by Prather (105, 106), namely, pain and tenderness in the lower quadrant on the corresponding side of the injury in conjunction with psoas spasm, appearing from 12 to 36 hours after the injury, which are diagnostic of extravasation of blood and/or urine. They indicate true rupture of the kidney long before blood pressure or pyelographic changes makes one suspicious of such an eventuality. They were observed in 3 of our cases, and were of inestimable value in establishing an early diagnosis in each instance.

Peritoneal irritation. Nausea, vomiting, hiccup, and signs of paralytic ileus may be reflexly produced by the injured kidney. These may so dominate the picture within a few hours that the possibility of an abdominal injury is strongly entertained, especially in the cases in which there is an absence of hematuria. As a general rule, if the abdominal signs are reflexly produced, they tend to subside or disappear within a short time, where-

as, if there is an actual intraperitoneal injury, they tend to persist and increase. Difficulty in differential diagnosis may be encountered in instances in which laceration of the peritoneum occurs in association with a kidney injury without any injury to an abdominal viscus, as was seen in one of our cases.

Suppression of urine. A variable diminution in the urinary output is usually noted. This is due to the temporary suppression of the injured kidney, to possible ureteral occlusion by blood clots, or to an injury to the ureter or pelvis on the affected side. Reflex suppression on the normal side has been reported and was seen in 2 of our cases. The urinary suppression, as a rule, subsides quickly and is soon followed by polyuria. A period of extended suppression may denote a severe injury to both kidneys, to one kidney with severe reflex suppression of the uninjured kidney, or an injury to the only good kidney that the patient possesses.

Associated injuries. An injury to the kidney may be associated with injury to other regions, namely, fracture of the last two ribs, fracture of the transverse processes of L 1, 2, 3, and 4 on the affected side, or contusion or rupture of the liver or spleen, or of both. Coincidental damage to the pancreas offers a grave prognosis, but the most serious of all is an injury to any part of the intestinal tract. Of injuries to the kidney and thorax, 40 per cent are associated with intrathoracic lesions (50). Fracture of the skull, concussion of the brain, and fractures of other bones of the body (including the pelvis) have also been found as associated injuries. Serious associated lesions were present in 19 cases and absent in 8 cases of our series. Their prevalence and wide distribution, and the fact that they are usually more serious than the kidney lesion itself illustrates how important they are in the course and management of renal trauma. Three of the 4 deaths were due to an associated lesion.

Coincidental findings

1. If bleeding is profuse, or if there is an associated injury of the liver or spleen, there is a rapid fall of the red blood count and hemoglobin. Leucocytosis, which develops in a short time after the injury, subsides quite quickly unless extravasation is present and infection supervenes.

2. Some fever, usually low grade, is common soon after injury to the kidney in more than 50 per cent of the cases, unless shock is present. This soon subsides and may again appear about the fifth day because of resorption of blood from the retroperitoneal space. Sudden elevation or persistence denotes serious infective complications.

3. In some patients a secondary anemia out of all proportion to the degree of trauma or to the

ORKIN MANAGEMENT OF TRAUMA TO THE KIDNEY

amount of hemorrhage may appear on the fourth or fifth day (140) This is a toxic phenomenon and was observed in 6 patients in our series

4 Bile in the urine and jaundice denote injury to the liver Some degree of cyanosis may be observed in those patients who are in some degree of shock, or in those with an injury to the lung with hemothorax, pneumothorax, or both Air hunger may be seen at times in patients who are bleeding profusely

DIAGNOSIS OF RENAL INJURIES

The diagnosis of a renal injury in the majority of instances is relatively simple A history of an accident, with or without external evidence of injury, pain and tenderness in the kidney area, and the finding of hematuria, more than suffices to warrant a diagnosis of trauma to the kidney However, in some cases, even after a careful critical examination, one may not be able to make an exact clinical diagnosis In these instances, the history of trauma may be trivial or absent and the external evidence of injury may be lacking In addition, as I have previously outlined, the symptoms may be confusing or misleading, or vital subjective and objective findings may be missing This is true especially in those cases in which we have associated visceral or bony injuries of such magnitude that the latter injuries are considered as of paramount importance and the kidney injury as trivial in nature Equally disconcerting are those cases in which, for one reason or another, no blood is found in the urine Backus recently reviewed 7 cases in which the presenting signs and symptoms were those of an acute abdomen In all but 1 of these cases, the mistaken diagnosis had led to exploratory laparotomy with negative abdominal findings before the true underlying pathology of renal injury was realized We have recently had such a case at Beckman-Downtown Hospital (Fig 1), of a young man who after a fall on his buttocks in the bathtub apparently sustained a trivial kidney injury in that he had no distinctive loin tenderness and only from 10 to 15 red blood cells per high power field in the urine The presenting symptoms were those of a ruptured intra-abdominal viscus A simple abdominal film disclosed what was interpreted as free air under the diaphragm and he was explored by the surgeons with negative abdominal findings Urological investigation later disclosed an intraparenchymal rupture of the upper calyx of the left kidney

In a very small number of instances the renal injury is so extensive, or the associated injuries are of such magnitude, that the individual dies

Fig 1 Simple abdominal film interpreted as showing free air under the diaphragm in a patient admitted with abdominal rigidity after a fall on his buttocks The exploratory laparotomy was negative. Urological investigation later disclosed an intraparenchymal rupture of the left kidney

before or soon after he reaches the hospital Fortunately, however, in the great majority of injuries to the kidney, the trauma sustained does not immediately threaten the life of the individual

Following an injury that may in any way conceivably involve the genitourinary system, an immediate and complete physical examination should be made, with care to note whether any complicating associated injuries exist It should be remembered that complicating injuries of the brain, abdominal viscera, and chest may be latent in manifesting themselves

If there is hematuria, it is first necessary to rule out rupture of the urethra and bladder Roentgenograms will disclose fracture of the pelvis Ruptures of the urethra will soon make themselves evident locally If the bladder is suspected, late films of the bladder in the excretory pyelograms will be of help, and may show intraperitoneal or extraperitoneal extravasation Signs of fluid in the peritoneal cavity and of peritonitis should be carefully looked for All patients should be made to void soon after admission and the urine carefully studied Subsequent urines should also be examined If the individual cannot void, he

a

b

Fig 2 Simple abdominal film in a case of rupture of the right kidney showing the gas that may be associated with a rapidly developing paralytic ileus a, No information is discernible concerning the kidneys b, Treatment with the Miller Abbot tube

should be gently catheterized to distinguish between inability to void due to the severe pain of the injury, urinary retention due to clots in the bladder, and a possible ruptured bladder or urethra. Six of our patients were catheterized because of inability to void and in each instance renal trauma was suspected after finding gross blood in the urine.

Since there is no relation between the intensity of the traumatism, the clinical signs, the symptomatology, and the gravity of the renal lesion, the patient should be investigated urologically as quickly and completely as is possible. It is only by this approach that a genuine anatomicopathologic diagnosis can be made, which is so necessary in the evaluation of conservative versus operative interference. The following methods have been proposed for urological investigation (1) simple roentgenography, (2) excretion urography, and (3) cystoscopy and retrograde pyelography.

SIMPLE ROENTGENOGRAPHY

A simple film of the abdomen should be made soon after admission and may give an initial lead as to the injury. It may even be made while the

patient is receiving treatment for shock. Under excellent circumstances, the following data may be discerned on the simple film (2, 55, 86, 115)

- 1 Absence of the renal shadow
 - 2 Enlargement of renal shadow due to subcapsular hematoma
 - 3 Obliteration of the psoas line
 - 4 Scoliosis of the spine with concavity toward affected side due to reflex muscular spasm
 - 5 Raised hemidiaphragm—found more often on the left side
 - 6 Extraperitoneal hematoma—large soft tissue mass of slightly greater density than remainder of the posterior abdominal wall
 - 7 Associated bony injuries—fracture of the eleventh and twelfth ribs, fracture of the bony pelvis, and injury of the lumbar transverse processes or vertebrae
 - 8 Air under diaphragm—representative of ruptured viscus
 - 9 Fluid levels in dilated loops of bowel
- However, except for the demonstration of a grossly enlarged kidney on the affected side, of air under the diaphragm, or of associated skeletal fractures, the simple film is disappointing and

Fig 3 Excretory urography performed at the bedside using a portable x ray unit. The patient had fallen down an elevator shaft and had sustained a fracture of the twelfth thoracic vertebra, and the left tenth and eleventh ribs. There was marked tenderness in the left loin. He was bleeding moderately from the urinary tract and he was in shock. Because of these normal pyelograms, the patient was treated conservatively.

Fig 4 Trauma to the right kidney. Intravenous pyelograms demonstrate a dilated pelvis and ureter on this side with filling defects interpreted as blood clots. No evidence of extravasation. At operation there was a large rent bisecting the kidney in the region of the pelvis roofed by the blood clot.

does not, as a rule, supply valuable information (2, 22, 115). The film is usually not diagnostic because it is largely obscured by gas associated with a rapidly developing paralytic ileus (Fig 2). In my experience, the simple film was of value in 13 cases in determining associated skeletal injuries. In my cases it was either misleading or not diagnostic as applied to the renal lesion. In instances of dire emergency, one may have recourse to a simple film, but, if at all possible, once the patient is out of shock, one should perform excretory urography. Certainly, if the exigency is such that emergency surgery is contemplated, it is imperative to at least take a simple film in order to attempt to demonstrate that another kidney shadow exists besides the traumatized one.

EXCRETION UROGRAPHY

Excretory urography has been recommended by many but employed by too few people as a routine procedure in every case of potential renal injury. Storck has re-emphasized its value and has plead-

ed for its wider use, even at the bedside if the patient cannot be moved (Fig 3). Intravenous pyelography is simple of execution, free of potential infection, and may give valuable information if properly interpreted.

Although the optimal time for doing an intravenous pyelogram should be determined for each patient, it would appear from the reported experimental and clinical evidence that the best pyelograms are obtained immediately after the injury (149). Stirling and Lands (142) were able to make a positive diagnosis from initial pyelograms in 23 of 34 cases, while Ferrer and Knigge were able to make a conclusive diagnosis in 44 of 53 (82%) severely injured cases. Similar experiences are reported by Hareide, Wood (164, 165), and Schenck. McKenna has reported several cases of rupture diagnosed by excretory urography and confirmed by operation. Prather (105) has described instances of lack of function soon after admission, but function became evident in from 5 to 7 days. It would appear from this that if the initial pyelogram shows no excretion or if it is unsatisfactory, it should be repeated within a

few days. Most men do not advise excretory urography if the patient is in shock, or if the blood pressure is below 90 mm systolic. The decided value of intravenous pyelography even in such circumstances is illustrated by a case of William Ginzberg. This patient was a female who had suffered a severe injury in an automobile accident. On admission to the hospital, she was in shock with a blood pressure of 78 mm Hg, and she was bleeding profusely. X-rays revealed a large soft tissue mass on the injured left side with a non-functioning kidney and a perfectly functioning right kidney. Nephrectomy was done with a great deal of assurance that the patient's remaining kidney was perfectly normal. The following information may occasionally be gathered from excretory urography (53, 86).

Injured side

- 1 Normal or relatively normal pyelogram—minor injury
- 2 Diminution or absence of excretion on affected side
 - poor shadow or absence of dye due to
 - a Actual renal damage
 - b Pressure of extrarenal hematoma
 - c Reflex from shock
 - d Too long a delay in obtaining pyelograms
- 3 Deformity of pelvis or calyces due to actual destruction or blood clot
- 4 Extravasation of the dye
 - a Within the kidney parenchyma
 - b Outside the renal capsule
- 5 Displacement of ureter, ureteropelvic junction, or both

Noninjured side The presence and function of the opposite kidney. Turton and Williamson have reviewed 5 cases in which trauma was sustained by a congenital solitary kidney, and in 4 of these nephrectomy was unwittingly performed. Although congenital solitary kidney is not frequent, congenital hypoplastic kidney occurs frequently enough to make one extremely careful before doing a nephrectomy for renal injury without having demonstrated a normal kidney on the contralateral side (135). Although some hypoplastic kidneys may sustain life, the majority will not.

From the foregoing, it can be seen that excretory urography is of great diagnostic value immediately following renal injuries. Its immediate usefulness is found in the cases in which the injury is minor or moderate and in which the secretory power is not disturbed. If the ruptured kidney is damaged to such an extent that its secretory power is reduced or abolished, the pyelo-

grams will be of little value except perhaps to demonstrate a good contralateral kidney. If a ruptured kidney with multiple fractures and a large perirenal hematoma is excreting the dye, the extravasated urine is mixed with the media and can be demonstrated only with great difficulty. Further, in severe renal injuries, by the time the patient has recovered from shock and sufficient urinary output is present to warrant utilization of excretory urography, intractable ileus and abdominal distention supervenes to further obscure the films.

The experimental findings of Stirling and Lands (142), and of Domrich, that excretory urography aids in locating the side involved and the gravity of the lesion, but that it does not reveal the extent or type of injury, has been confirmed by clinical experience. Hamilton Bailey states that in his experience he has had disappointing results with excretory urography in assessing kidney damage on the affected side. This has been reiterated by McGregor, Adams, Sargent (122), Foulds and Shannon, Farman, Gordon-Taylor, Scholl (127), Mathe (82), and others.

In one of my first cases of renal trauma, excretory urography revealed a dilated pelvis and ureter filled with blood clots, with no evidence of extravasation (Fig 4). The patient was treated conservatively for 2 weeks, at the end of which time operative interference was undertaken because of persistent and increasing hemorrhage. Nephrectomy was performed but the patient died soon after operation. The specimen showed a large rent roofed by blood clot, almost bisecting the kidney in the region of the pelvis. I feel quite certain that had a retrograde pyelogram been done in this case, extravasation would have been demonstrated, and operative interference undertaken much earlier, thereby perhaps saving this man's life. Excretory urography gave me a false sense of security in this case which was not justified by the existing pathology.

In another case excretory urography disclosed an intraparenchymal rupture, and the patient was treated conservatively, the hematuria ceasing on the third day. Ten days later he had a sudden profuse secondary hemorrhage warranting operative interference. This disclosed a large rent in the upper pole, and nephrectomy was performed with good result. Here too, I feel that if retrograde study had been done, the patient would have been operated upon sooner.

In some of my cases, as illustrated in Figure 5, the excretory pyelogram of the injured kidney may appear normal, but retrograde study of the traumatized organ may demonstrate extravasa-

Fig 5 Trauma to the right kidney a, Intravenous pyelograms demonstrate normal right pyelogram b, Retrograde pyelogram on this side indicative of extravasation At operation, a ruptured hypernephroma of the upper pole was found

tion On several occasions, I have found no excretion of the contrast substance to be present on the injured side, but on retrograde pyelography, I had a perfectly good pyelogram demonstrative of either a normal pelvis or unmistakable evidence of extravasation

In addition, observation cystoscopy at the time of the retrograde study may also be helpful in visualizing the interior of the bladder, in studying the ureteral efflux and indigo carmine excretion of both kidneys, and in unplugging a ureter filled with blood clot Two cases in my experience illustrate this point strikingly One was that of a patient admitted to Beckman-Downtown Hospital whose foot was caught by a tow rope while working on a ship, he was thrown to the floor striking his left loin and sustaining a fracture dislocation of his ankle Because of the left loin pain and hematuria, excretory urography was performed This revealed a normal right pyelogram and an unsatisfactory but apparently normal left pyelogram, and he was treated conservatively However, because of persistent and profuse hematuria with clots which lasted longer than 24 hours, he was examined with the cystoscope This revealed a large ulcerated bleeding bladder carci-

noma which was immediately fulgurated The left ureteral efflux was only slightly blood-tinged, and the left pyelogram was fairly normal His further urological progress was uneventful Another case was that of a man whose right loin was struck by a log flying off a sawmill He was admitted in shock, bleeding profusely, and was given supportive therapy When he had recovered sufficiently, excretory urography was performed This revealed a normal pyelogram on the right side with no evidence of extravasation, there was no excretion from the left side Because of his persistent and profuse bleeding, he was examined with the cystoscope on the following day, this revealed the bleeding to be coming from the right side, and careful inspection of the bladder showed no left half of the trigone and no left ureteral orifice It was quite evident that we were dealing with a traumatized congenital solitary kidney Although the condition improved with conservative treatment, the knowledge obtained by cystoscopy would have been of inestimable value had surgical intervention been necessary

Because of this accumulative experience and evidence, I now strongly agree with Sargent (122, 123) and Farman that cystoscopy and retrograde

pyelography should be routine as this gives a much better pyelogram and demonstrates extravasation, when present, much more assuredly and definitely than excretory urography. Although excretory urography was done 20 times in this series of 27 cases, satisfactory pyelograms for diagnosis were obtained in only 6. Extravasation was demonstrated in only 1 instance, and missed in 5 cases. Two of the latter cases were diagnosed at operation, and 3 by retrograde study. In another instance, extravasation which was suspected as being present on the intravenous pyelograms was not confirmed on the retrograde. Cystoscopy also occasionally gives us valuable information concerning concomitant lesions in the bladder.

The argument against retrograde pyelography has concerned itself with the danger of introducing

infection and increasing or reactivating bleeding. Redi, Gutierrez and Farman (45) believe that this is more theoretical than actual. That the retrograde dye acts as an irritant on the traumatized renal parenchyma has been disproved by Campbell and Lynch. In answer to the statement that retrograde pyelography may disseminate infection, I can only state that most urologists believe that if there is extravasation of blood, urine, or of both, infection may supervene without retrograde injection of the contrast substance. In a careful review of the literature, I have been able to find only 1 instance of increased bleeding following retrograde catheterization. This was a case of Peacock's, but in this case also it must be remembered that secondary bleeding might have arisen even without cystoscopic manipulation. In my experience, I have not encountered a single instance of aggravation of the general signs or increase of the hemorrhage or the size of the hematoma. This procedure has been of inestimable value in the instances in which I used it, and it might have saved the only patient who should not have died in this series, had I used it. However, I wish to caution that if retrograde study is performed, it be done under strict aseptic technique, and that the dye be instilled by the gravity method as recommended by Wesson.

If we admit the possible hazards of retrograde pyelography, their sum total does not equal the danger of case management without it. The only reliable and scientific basis for an anatomicopathological diagnosis as to the type and extent of the injury is by retrograde study, so necessary in the evaluation of conservative or operative intervention.

MORTALITY AND COMPLICATIONS

A study of Table I in which mortality statistics have been collected up to the year of 1937 suggests that the mortality in renal trauma, whatever the treatment, is high, averaging over 20 per cent.

In the larger series of collected statistics, as reported by Riese, Watson, Suter, Lardennois, Keller, Ponomarett, and Osgood, the mortality figures would seem to favor operative interference as against expectant treatment. These early statistical reports, still quoted by recent textbooks and writers, are in some measure valueless and misleading as applied to the present-day management of renal injuries. In the years from 1938 to 1948 (Table II), there has been a decided decrease in the death rate from renal trauma.

There was no mortality reported by Mertz, Priestley, Harrison, Cheetham, and Adams, for patients treated expectantly or by operation. A

¹Severe associated lesions.

review of the reports of Prather (106), Robertson (115), Fernier, Lynch, and Orkin reveals that the total mortality in their series varies from 11 to 27 per cent. If one eliminates from consideration the patients who enter the hospital in a moribund condition or with very severe associated injuries, the mortality rate drops to about 4 per cent.

The reasons for this marked reduction in mortality are not difficult to find according to Scholl (127). Modern accurate diagnostic measures, a better knowledge of the pathology resulting from renal trauma, a clearer understanding of the criteria for surgical intervention, blood banks and the more generous use of available blood, skillful conserving parenchymal plastic procedures, and efficacious, widely used antibiotics have all served to improve the prognosis. On the other hand, despite all of these influences, the mortality will always tend to be high in certain types of cases.

One type includes those instances in which the patient is exsanguinated or severe rupture of the kidney because of either pulpification or severe rupture of the kidney. Schenck and Osgood had 4 such cases in their series. The mortality will always be high in complicated cases. Laewen, quoted by Strauss (145), reported a series of 57 cases of gunshot wounds, there were only 5 cures, a mortality of 87.7 per cent. The results of Wallace, Lockwood and his coworkers, Fraser and Drummond, and Walters and his associates published in 1917 and later reviewed by Young for the Surgeon General's report, covered a series of 2,121 cases of gunshot wounds of the abdomen. The kidney was involved in 155 instances, and there was a mortality of 57 per cent. There were 13 cases of stab and gunshot wounds of the kidney with 6 deaths due to intra-abdominal involvement. In Fernier and Knigge's series. The association of a ruptured liver or intestines and a ruptured kidney carries with it a mortality of from 50 to 72 per cent. Desjardes reported a 50 per cent mortality for coincidental injuries of the spleen and kidney. In addition to intra-abdominal involvement, one may encounter severe general or skeletal injuries. Fernier and Knigge had 31 such cases, and in our series 2 patients died with minor renal lesions—one with a gas bacillus infection of a traumatic amputation of the leg, and the other with a severe injury to the chest and shift of the mediastinum.

In Table II, in which there is reported the mortalities of the period from 1938 to 1948, I have marked the mortalities with a superior number 1 in the instances in which I felt that severe associated complicating injuries were of such magnitude as to alter the mortality greatly. In most of these, the renal injury was of minor consequence and the

complicating injury was undoubtedly the cause of death. For example, Prather (105) observed the immediate death of 2 patients within 4 hours of injury before shock could be terminated to permit surgical intervention. One of his operative patients died from laceration of the liver and peritonitis. There were 4 deaths in Robertson's series (115), 2 operative and 2 nonoperative. The 2 nonoperative deaths followed gunshot wounds, one injuring the lung, spinal cord, and kidney, and the other injuring the kidney, abdominal viscera, and lung. The operative deaths were due to anuria and a fractured kidney, respectively. In the total series of 137 cases reported by Fernier and Knigge, there were 37 deaths, a mortality of 27 per cent. In their series, the kidney injury was named as the cause of death in only 5 of the 31 cases of severe general injuries. If we consider merely these 5 cases, it leaves 5 instances in a total of 111 cases, a mortality of 4.5 per cent. In our series of 27 patients, there were 4 deaths, 2 operative and 2 nonoperative. Of the operative deaths, 1 occurred in a case of ruptured liver, spleen, bladder, and urethra in addition to the kidney injury. Of the nonoperative deaths, one was of a patient with a gas bacillus infection resulting from traumatic amputation of the leg, and the other was of a

patient with a ruptured lung and shift of the mediastinum. The renal injury was of a minor degree in each of these cases. If we consider only 1 of the operative deaths as uncomplicated, leaving out the 3 in which the associated lesion was responsible for the individual's demise, we have 1 death in 24, a mortality of 4.1 per cent.

Although in the last 10 years there has been a decided decrease in the death rate due to trauma of the kidney, numerous men have pointed out the occurrence of an astoundingly large group of complications as an aftermath of such injury. These serious after effects, which often require nephrectomy for their cure, usually occur in the patients with ruptured kidney who have been treated expectantly. Cheetham saw 25 patients with late complications at various intervals after the trauma. Three could be treated medically and 22 had to be operated upon. Dozza (38) reported 82 cases of injury to the kidney. Operation was performed in 3, and conservative management was satisfactory in 79. Twenty-seven of the patients, seen from 6 months to 30 years after the injury, had to be operated upon for consequences of the renal injury. In Priestley and Pilcher's series (109) of 45 patients treated medically, 25 per cent had symptoms referable to their injury. Colston and Baker (23) presented 13 cases which came under their personal observation at periods varying from 4 months to some 30 years after the trauma, among which they found cyst formation in 6. These authors state that while it is not their purpose to condemn conservative treatment of kidney injuries, they believe that the surgeon must be completely familiar with the changes which may occur in the kidney or perirenal tissue as a late result of the injuries and that he should take the proper steps to prevent their development. In our series of 27 patients, there were 6 with a ruptured kidney who were treated expectantly. Follow up after 5 years revealed that the result is poor in all. In 2, a large cyst is present at the lower pole of the kidney, and in 4, kidney function as determined by excretory urography and indigo carmine excretion is shown to be reduced to 25 per cent or less of normal.

Obstruction at the ureteropelvic junction by stricture, band, or adhesions due to a more or less complete division of the ureter in this region or to a periureteral inflammatory reaction often leads to hydronephrosis or pyonephrosis (26, 42, 57). An acute perinephritic abscess may develop in the course of breakdown of a hematoma, or localized necrosis of the kidney (26, 57). In the chronic form, following degeneration of the hematoma, there may be the formation of a perirenal collec-

tion of fluid between the fibrous capsule and the kidney or in the fatty capsule, with the formation of perirenal cysts or pseudohydronephrosis (144) (Fig 6).

Fibrous perinephritic changes may produce some degree of compression and atrophy of the kidney with resultant chronic pain (20). Persistent pain may also result from involvement of nerves in scar tissue. Although Cabot (16) doubts the possibility of nephroptosis, O'Connor found 12 instances of this condition which could be classified as being definitely post-traumatic. Lazarus reported a case of renal calculus developing 13 weeks after an injury. Sklarz and Cabot (16) report post-traumatic calculi around a coagulum (Fig 7). Kindall had several cases in which the renal calculus was in close proximity to the renal scar. Interference with the blood supply may produce atrophy of the kidney. Some people have supposed that the vascular damage incident to the trauma may conceivably produce a partial ischemia and hypertension (91, 148). This has not been universally accepted as Braasch, in a review of 50 cases with clinical evidence of renal trauma, found that in only 1 instance was renal injury a possible factor in the causation of the hypertension.

Instances of renal tumor following injury have been cited by Bonar and others, but this also is difficult to evaluate. Other late complications that have been mentioned are persistent urinary fistula and secondary bleeding subsequent to conservative surgical interference.

The more widespread use of excretory and retrograde pyelography has served to unearth the ever-increasing number of complications. In addition, these procedures have brought out the fact that although the ruptured kidney may heal without any of these after effects, a definite and marked diminution in its function may occur. Wesson (156) believes that subcutaneous ruptures of the kidney may heal without operation and with a functional loss of about 50 per cent. The late results in several of my cases have shown that this functional loss may be even greater than that predicated by Wesson.

In contradistinction to the aforementioned complications that may follow renal ruptures treated expectantly, I have been impressed with the end result, as have others who have advocated conservative surgery in these cases. The freedom from symptoms and the excellent functional picture as determined by roentgenography and function tests justify in my mind a continuation of this plan of treating true rupture of the kidney (Figs 8 and 9).

Fig 6 Injury to right kidney 5 years before at which time a rupture of the kidney with a large hematoma was found. The patient was treated conservatively. At the present time, intravenous pyelograms demonstrate a distorted picture with a large cyst of the lower pole on the right side.

Fig 7 Injury to left kidney 4 years ago. Intravenous pyelograms demonstrated a large calculus with no function in the left kidney. Retrograde study revealed a distorted upper ureter and a large calculus in the kidney with no excretion of indigo carmine from this side. At operation, the upper ureter was severely strictured. The calculus on chemical analysis contained a blood clot as its nidus.

TREATMENT OF RENAL INJURIES

The implication in the more recent literature concerning the treatment of renal injuries has been that the majority of deaths are due, on the one hand to the severity of the primary injury, and on the other, to procrastination in exploration. Since there are two general groups of cases, namely, those complicated by other injuries, and those with renal injury alone, and since each group may vary in severity, it is immediately evident how difficult it is to be dogmatic or to establish any standard rule in the management of renal trauma. While every case must be considered individually, it seems to me that in order to attain a successful end result in any patient, the following factors must be considered in every instance of renal trauma.

- 1 Prompt recognition of any intra-abdominal trauma or other associated lesions
- 2 The magnitude of the renal injury
- 3 Prompt decision if operation is necessary
- 4 The correct time for, and the type of, operative interference

In addition, if one keeps in mind the necessity of stopping hemorrhage early and of combating infection later on, a correct decision concerning management will more often be made than not.

In some cases, the injury to the kidney is so extensive, or the associated lesions are of such magnitude (or both) that death occurs almost immediately. Patients who sustain a laceration of the renal vessels succumb before or soon after they are admitted to the hospital. Fortunately, immediate exitus does not occur in the majority of instances of extensive injury to the kidney or associated lesions (or both), and the patients, as a rule, are admitted to the hospital in shock. The latter is due to the pain of the trauma, the severe injury, and the loss of blood, and should be combated with all available means—external heat, intravenous fluids, plasma, and blood. Morphine should be withheld until a careful evaluation of the abdominal findings have been made. Estes has recommended that the treatment of shock be carried out close to the operating room in order to have as

For reasons previously enumerated, I agree with Sargent (124) that cystoscopy and retrograde pyelography should be routine in every case of renal injury and should be done wherever feasible as soon as possible.

In the management of patients in whom the kidney only is involved, there is one important question whether to intervene surgically or to treat the patient expectantly. This has met with divergent opinions. One group (2, 12, 98) has believed that the treatment should always be conservative unless absolute indications for operative interference arises. Another group headed by Lowsley (75) believes that it is conservative to explore if the hematuria lasts longer than 24 hours. Still another group is of the opinion that in view of the possible dangers and sequelae following renal injuries and the slight risk of exploration, surgical interference should be early and frequent rather than late and rare (23, 165). The adherents of the last two opinions state further that the proponents of conservative treatment should realize that surgical interference does not imply nephrectomy, but an attempt to conserve the kidney by drainage and arrest of bleeding. Early exposure enables one to inspect the kidney and make the necessary repairs, to practice conservative surgery and prevent secondary complications, and to perform a primary nephrectomy when indicated (165).

The indications for immediate or emergent operation are determined entirely by the clinical picture of grave hemorrhage and/or signs of an associated intra-abdominal lesion. The indications for delayed surgical interference have never been universally agreed upon and seem to have been limited to those cases in which the clinical picture as described does not improve. I believe that pyelographic evidence of extravasation should determine the need and should be the basis for delayed surgical interference before any deterioration in the clinical picture makes such intervention necessary. I again wish to reiterate that from my experience and that of others, I believe that retrograde pyelography is the only absolute method of establishing an anatomicopathologic diagnosis so necessary in the further management of these cases. By this method it is possible to decide what type of injury has been sustained, and one can institute the necessary treatment with reasonable assurance and avoidance of possible sequelae.

Statistically, contusion of the kidney (Type 1 and 2 injuries) makes up about two-thirds of all renal injuries, and true rupture (Types 3 and 4) about one-third. It is universally agreed that if

the diagnosis has been definitely established as that of a contusion, the patient should be treated conservatively and kept in bed at least 2 weeks (94). O'Connor and Adams have presented cases in which there was a recurrence of bleeding in patients gotten out of bed too soon. One of my patients with an intraparenchymal rupture of the kidney stopped bleeding 5 days after his injury and on getting out of bed the next day began to bleed so profusely that emergency nephrectomy had to be performed. In the conservatively treated contused kidney, clinical improvement is usually noted and the further course is uneventful. If, as may rarely happen, the primary or secondary bleeding becomes profuse and uncontrollable or if sepsis supervenes, re-evaluation of the condition and possible operative interference become necessary.

The opinions concerning the treatment of true rupture of the kidney (Types 3 and 4) are very divergent. One group feels that this type of case should be treated conservatively unless persistent and profuse hemorrhage warrants operative intervention. It is of the opinion that if nephrectomy becomes necessary, it may be done at a later date. Another group feels that this type of injury should be subjected to operative interference. The experimental findings of Stirling and Lands (140), and the clinical experience cited by Wood (165) and Prather (106) stress the fact that while true rupture may at times heal without complication, this is the exception rather than the rule. The feeling would seem to be that earlier surgery may result in greater conservation of renal tissue with no increase in loss of life. To be more specific, too long delayed surgery in a true rupture may result in irreparable infection and necessitate nephrectomy, while comparatively early surgery, after the period of shock is passed, should decrease our mortalities and nephrectomies. In accordance with my experience, I subscribe to this view wholeheartedly.

The time to operate has to be determined in each case. If it is done too early, the result may be fatal. If, however, in the face of alarming bleeding, one procrastinates, hemorrhage and shock may occur. In the absence of a peritoneal tear or injury of an intraperitoneal viscus, the emergency of a ruptured kidney seldom demands immediate operative interference. Wood (106) believes that exploration is more easily and safely carried out 3 or 4 days after the injury. If a patient is operated upon too early, he may bleed profusely and fatally once the clots are evacuated. This delay in time allows the small vessels to contract and the clots to organize. It also permits

provement in the patient's general condition by the administration of blood and other aids. Further, opportunity is afforded during this recovery period for an evaluation of the clinical and roentgenographic findings, and operative intervention can be done with a greater feeling of assurance. In addition, if infarction of part or all of the kidney occurs, this will be visible to the surgeon at the end of 72 hours.

In the treatment of wounds of the kidney there are three possible surgical procedures according to Scholl (8, 9, 127): (1) drainage of the renal region with or without decapsulation, (2) partial nephrectomy and repair, and (3) nephrectomy.

1 *Drainage of the renal region* This is the simplest procedure and may be done quickly with minimal risk to the patient. It is indicated in those conditions in which time or the condition of the patient contraindicates extensive surgery, and in those instances in which a good contralateral kidney cannot be demonstrated. Foreign bodies and loose fragments of tissue should be searched for and removed. Drainage should be free and adequate by means of many Penrose drains. The use of tampons, although condemned by Wesson (156) as it may lead to sinus formation, may in selected cases be lifesaving. A large infected perirenal mass may be drained to improve the patient's general condition before nephrectomy. In some of these cases, further treatment may later be found to be unnecessary as satisfactory healing and progress may take place. In others, subsequent nephrectomy may have to be done, but with much less risk. If hemorrhage is encountered, every effort should be made to control it. Sutures of fine chromic catgut tied over fat may be used, or repair with ribbon gut according to the method of Lowsley (74, 75) may be employed. Oxygel or gelfoam may be placed over bleeding points or on the suture line. Kindall has reported a case of rupture of the kidney from the pelvis through the entire parenchyma which he repaired with complete functional recovery. Usually complete hemostasis cannot be obtained as one often encounters a continuous ooze in the field. Exposure through the loin permits firm packing, and this can be done with plain gauze. It is advisable to place a rubber dam under the packing as in this way the packing can easily be removed and there is no danger of secondary hemorrhage following such removal. If nephrectomy is contemplated but cannot be done because of either a deep short pedicle or a precarious condition of the patient, the area may be packed until such a time as secondary nephrectomy may safely be undertaken. If drainage is instituted, it

should be continued for at least 10 days. In some instances of severe parenchymatous infection or extravasation under the capsule, decapsulation may be performed. This relieves pain and tends to minimize any resultant cicatrization. Decapsulation may also be done in post-traumatic hydrocele of the kidney, such as was performed in one of my cases with complete relief of symptoms.

Mention should be made of the patient who has had a severe rupture of the kidney with a large perirenal hematoma upon whom operation cannot be performed either because of severe shock or severe associated lesions such as a fractured skull, laceration of the brain, ruptured lung, and the like. In the typical case, the patient has had a stormy course and has bordered on shock because of one or both of these conditions for a week or longer. At the end of this period, when the patient is no longer in shock and appears to be on the upgrade, surgical interference may be contemplated in an attempt to evacuate a large hematoma in the loin which may or may not be infected. Experience has shown that in this type of case, operation is fraught with grave risks. The patient may go into shock again, complete evacuation of the hematoma and blood clots is difficult, and drainage is almost impossible as the entire retroperitoneal area is involved. Indeed, some of the areas may pocket off, and become reinfected. In some of these instances, a patient who seems to have weathered the storm with expectant treatment, may, with operative incision and drainage, and evacuation of the clots, be converted to a severely infected individual who rapidly becomes exhausted. It is my feeling that in this type of case, one might leave well enough alone and chance the risk of post-traumatic renal sequelae.

2 *Partial nephrectomy and repair* Even under ideal conditions, partial nephrectomy and plastic repair may be unsuccessful. Cases have been reported in which the lower pole of the kidney was knocked off and mattress sutures tied over fat were used to close the defect and arrest the bleeding, in which a satisfactory functioning hemikidney was obtained. As a general rule, this procedure is not recommended for various reasons. It is difficult and time-consuming, and carries with it very little likelihood of success in an infected wound. Extensive plastic procedures on the pelvis or upper ureter may produce a functionless kidney, and necrosis and late bleeding may necessitate a secondary nephrectomy. Also, partial nephrectomy is not likely to remove the cause of the bleeding in a patient already depleted. It would seem to be poor judgment to expose him to a fresh hemorrhage from suture.

If the ureteropelvic junction is partially torn, repair over a splinting catheter with nephrostomy drainage might be successful. If the lower pole of a solitary kidney has been avulsed, closure of the defect and control of the hemorrhage with mattress sutures tied over fat becomes imperative.

3 *Nephrectomy* is simpler than most conservative operations. It removes the cause of bleeding and the potential field for infection. It is also less time-consuming. It eliminates the possibility of future bleeding and secondary operations either as a result of the primary operative procedure or of the late sequelae. Nephrectomy should never be done unless one has demonstrated a good contralateral kidney. It is indicated in the following situations:

- 1 Extensive destruction of renal tissue
- 2 Multiple deep lacerations
- 3 Grossly torn or injured pedicle
- 4 Irreparable damage of the pelvis, ureter, or both
- 5 Persistent or marked secondary bleeding
- 6 Tear into a short pedicle preventing delivery of the kidney for a conservative procedure
- 7 Hydronephrosis or other serious disease of the kidney
- 8 Persistent urinary sinus
- 9 Cortical abscesses of the kidney

Nephrectomy however, is rarely indicated immediately after the injury. It is extremely hazardous and carries with it a high mortality because of the facts that the patient has just come out of shock, the tissues are extremely friable, and profuse and fatal hemorrhage may arise on freeing of the fresh blood clots. Increased experience has shown that better results are obtained by waiting 3 or 4 days after the injury if possible, and if at that time nephrectomy cannot be safely performed, it is much wiser to drain and pack, and leave the nephrectomy till a later date. If it becomes urgent to remove the kidney and the pedicle is friable or extremely indurated, it is much safer to leave the pedicle clamps in place following nephrectomy rather than to attempt tying the pedicle with the risk of the suture's slipping off or cutting through. The clamps may then safely be removed in 7 days in the operating room under gas anesthesia. In any operation on the kidney for trauma, it should be remembered that the field is infected and it is good judgment to close only about half of the wound. This will prevent deep infections of the kidney and wound.

The care of the late sequelae, such as kidney abscess, perirenal suppuration, subphrenic abscess, hydronephrosis, pyonephrosis, and of other complications is based on the principles of

treatment of these conditions, whatever their etiology may be.

Throughout the management of renal trauma, be it conservative or surgical, one should make use of blood and the appropriate chemotherapeutic agents as the case requires. Both conservatively and surgically treated patients should be checked with excretory urography and retrograde studies. These should be repeated at regular intervals for at least 10 years in order to determine and treat any secondary complications that may arise. It is only by following all cases of renal trauma over a long period of time that adequate statistics can be set up to determine whether the principles which have been outlined in this article are correct.

SUMMARY AND CONCLUSIONS

1 An evaluation of the principles concerned in the management of renal trauma has been undertaken in order to answer several important problems relative to this subject.

2 A review of this and other series of renal injuries reveals that since there is no relation between the intensity of the traumatism, the clinical signs, the symptomatology, and the gravity of the renal lesion, the patient should be examined urologically as quickly and completely as possible. While a simple film and excretory pyelography should be done in every case immediately after the injury, even at the bedside if necessary, retrograde study is indicated as a routine procedure whenever feasible. It produces a better pyelogram and demonstrates extravasation, when present, much more assuredly than excretory urography. It is the only reliable and scientific basis for an anatomicopathologic diagnosis which is so necessary in the evaluation of conservative versus operative intervention.

3 Since 1937 there has been a decided decrease in the death rate due to renal trauma. The reported mortality is upward to 27 per cent, but if one eliminates the patients in a moribund condition or with severe associated injuries on admission, the mortality drops to about 4 per cent.

4 Despite the decrease in mortality, there has been an astoundingly large group of complications and a reduction in kidney function as an aftermath of renal injury. Experimentally and clinically, these complications occur in the cases of ruptured kidney treated expectantly.

5 In the patients who do not die soon after their injury, the indications for immediate or emergency operation are determined by the clinical picture of grave hemorrhage, a severe associated intraperitoneal lesion, or of both.

ORKIN MANAGEMENT OF TRAUMA TO THE KIDNEY

333

6 The indications for delayed surgery have never been agreed upon. I believe that the pyelographic evidence of extravasation should determine the need and be the basis for delayed surgery before deterioration in the clinical picture makes such interference necessary.

7 If the case is proved to be one of contusion in bed for at least 2 weeks is advised. If the case is one of true rupture (Type 3 or 4), early surgical interference is advised. This may best be done 3 or 4 days after the injury. Although the indications for nephrectomy have been enumerated, one should never nephrectomize a patient without having demonstrated another good kidney.

8 A careful follow-up of my series and that of others impresses me with the excellent end results of ruptured kidneys treated by conservative operative intervention. This clinical experience fortified by experimental evidence has justified a continuation of this practice.

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

HEAD

Complications and Sequelae of Untreated Fractures of the Facial Bones and Their Treatment F T MOORE and T G WARD *Brit J Plast Surg*, 1949, 1 257

Because facial fractures may not seriously affect the patient's general condition and because the general surgeon often does not have the training and equipment to treat them properly, these deforming injuries are often given little or no treatment, with the rationalization that the plastic surgeon may correct the deformities later if the patient so desires. It must be stressed that early treatment of such injuries is more convenient and effective for both patient and doctor than the treatment of a malunion with refracture, reduction, bone grafts, and other procedures which may be necessary at a later date. Co-operative effort of the plastic, orthopedic, neurological, and ophthalmic surgeons must be effective from the beginning to avoid extensive, multiple-stage plastic procedures to correct facial deformities later.

Fractures of the middle third of the face may result in multiple complications. Aside from the obvious deformity, they include nasal obstruction, anosmia, diplopia, lacrimal apparatus involvement, enophthalmos, injuries to the eye or optic nerve, malocclusion, and injuries to the maxillary division of the fifth cranial nerve.

If malunion of facial fractures has occurred, with any of these complications, the method of choice is refracture and realignment of the fragments. Immobilization is essential and is accomplished by the authors by means of a vertical rod in front of the face, fixed at its upper end to a plaster headcap and at its lower end to a bar attached to full cap splints on the upper and lower teeth. The movable fragment may then be pinned with a wire bowstring which is fixed to the vertical rod. Such an apparatus is illustrated in the original article. The orbital floors and other antral walls may be immobilized by packing the antra with ribbon gauze, which was left in place 37 days in 1 case. The antra are reached through incisions in the buccal sulcus.

A classification of maxillary fractures is presented, according to the location and direction of the fracture

EYE

Ocular Cysticercosis LECH JUNIOR *Am J Ophth*, 1949 32 523

The author discusses ocular cysticercosis from the following points of view history, pathogenesis,

casuistics, diagnosis, treatment, prognosis, pathology, prophylaxis, and iconography. He points out that cysticercosis of the eye is a rare disease which may be overlooked by an inexperienced observer. The diagnosis is especially difficult when only a single part of the parasite is found such as its hooks.

Schott and Sommering in 1829 independently observed the same cysticercus in the anterior chamber. Schott extracted the parasite. Siebold, in 1838, reported a subconjunctival cysticercus observed by Baum. Coccus reported a cyst in the vitreous resembling a cysticercus. In 1854 cysticercus in the vitreous and under the retina was reported by von Graefe who by 1866 had seen more than 80 cases among 80,000 patients.

Ocular cysticercosis follows the same laws of general infestation as cysticercus cellulosae, the larva of *taenia solium*. Heteroinfection is more common than autofestation. The parasite may be found in all the tissues of the eye except the lens. If an exudative inflammatory reaction occurs the following may develop: exudate, iritis, uveitis, purulent iridocyclitis, panophthalmitis, detachment of the retina, synechia of the iris, complicated cataract, and atrophy of the eyeball.

Ocular cysticercosis is a rare occurrence. There were 116 cases in a series of 54,000 patients, a ratio of 1 to 1,383. The first symptom is reduction in vision. If the media are clear, the cysticercus can be identified by its bluish white spherical vesicle with peripheral iridescent reflexes and slight undulatory movements and by its scolex which, when evaginated, reveals the sucking cups and when invaginated appears as a denser white spot in the center of the vesicle, if the media are turbid diagnosis is more difficult. The subconjunctival cysticercus resembles a lymphatic cyst from which it can be distinguished by a denser white spot in the center.

The complement fixation reaction in the blood is positive in 73 per cent of cases.

Although extraocular cysticercus is benign, intraocular complications usually result in blindness. The parasite, alive or dead, is destructive to the eye. Medical therapy and destruction of the parasite by caustics, diathermy, or electrolysis is ineffective. When it is situated behind the lens, extraction by the transcleral route is necessary. In 40 attempts, 34 extractions from the vitreous or from the subhyaloid area were successful. In 21 trials, 15 parasites were removed from beneath the retina, 7 of these being spontaneous extrusions after incision of the sclera and choroid. In early cases of subretinal cysticercus, extraction by means of diathermic localization under ophthalmoscopic control is recommended.

Control and inspection of meat, and personal and dietary hygiene, especially in rural areas, are necessary prophylactic measures

JOSHUA ZUCKERMAN, M D

Tumors of the Optic Nerve Long Survival in 3 Cases of Intracranial Tumor MAFTIN POSNER and GILBERT MORRAY *Arch Ophth*, Chic., 1948, 40 56

Tumors of the optic nerve may be classified into two general groups (1) intraneural tumors (the gliomas) arising within the nerve stem, and (2) extraneural tumors arising in the nerve sheath and comparable to the meningiomas of the brain. Additionally, a fibromatosis of the sheath is rarely observed. Any type of optic nerve tumor may spread intracranially or intraorbitally (or both).

Tumors confined to the orbit cause a painless unilateral exophthalmos followed by progressive amaurosis. Intracranial spread or origin may cause symptoms simulating those caused by other tumors of the chiasm or suprasellar region. The diagnosis of intracranial tumor of the optic nerve is suggested by unilateral exophthalmos and failure of vision, together with a normal visual field and central visual acuity in the other eye in a patient showing no other evidence of intracranial disease. Roentgenographic evidence of an enlarged optic foramen or erosion under the anterior clinoid process is significant.

Three patients, aged 8, 52, and 18, respectively, have been followed for periods of 12, 10, and 4 years after craniotomy and removal of optic nerve tumors. The chief complaint of all was a progressive reduction in vision of one eye ending in blindness. Two of the patients had a unilateral optic atrophy, while the third had a protrusion of the tumor into the eye at the disc, giving the appearance of papilledema which subsided after removal of the main growth. The long survival of these patients following surgery suggests that these tumors have not a uniformly hopeless prognosis, as was previously believed, and that patients are benefited even if the tumor is not completely removed. FRANK W. NEWELL, M D

EAR

Ménière's Syndrome Its Relation to Chemistry, an Etiologic Study GRANT SELFRIDGE. *Arch Otolaryng*, Chic., 1949, 49 1

The cause of Ménière's disease is unknown and has been ascribed variously to many things, such as high or low blood pressure, syphilis, infection, various metabolic disturbances such as those due to salt, potassium magnesium iodine, and calcium. No one has noted the relationship between nutritional disturbances and vertigo, which is the purpose of the present article.

Because of the lack of sufficient amounts of vitamin, particularly thiamine, nicotinic acid, riboflavin, pantothenic acid, and pyridoxine, plays a part in the aging process, one is justified in saying Ménière's disease is a function of the aging process. In one report of 33 cases all of the patients were over 50

years of age. In the other cases all of the patients of 40 years or older showed thiamine and nicotinic acid deficiency in the urine.

Allergy has been mentioned as a cause of vertigo. Grove stated that many patients presented extraneural symptoms—headaches, vasomotor rhinitis, gastrointestinal symptoms, insomnia, and urticarias.

The value of histamine in the treatment of Ménière's disease varies according to the authors, but the majority of the authors do not consider that it tells the whole story.

Many authors consider Ménière's disease to be due to disturbance of the water metabolism. In treatment the tinnitus was not much affected.

In summary and conclusion, the author states that deafness (and this includes Ménière's disease) is not related to one thing, but is related to all factors involved in growth, i.e., endocrine products, electrolytes, amino acids, and vitamins, including vitamin A. In the author's experience, patients with eighth nerve deafness with only slight upper tone loss recovered in a few weeks with thiamine chloride and nicotinic acid, while patients who had an abrupt loss did not show any recovery.

A review of the literature gives the impression that the most favorable results have been obtained from the use of several vitamins, and severance of the eighth nerve is not as popular as formerly. It hardly seems preposterous to make the claim that Ménière's disease is a chemical problem still requiring further study, and that it is related to nutritional and environmental factors. JOHN F. DELEH, M D

Ménière's Syndrome Observations on Vitamin Deficiency as the Causative Factor, The Vestibular Disturbance MILES ATKINSON. *Arch Otolaryng*, Chic., 1949, 49 151

In earlier articles the author described two groups of cases of Ménière's disease on the basis of the degree of reaction to histamine administered intradermally. In the group with a small response the condition was interpreted as being due to vaso-spasm and that with a strong response as due to a primary vasodilatation.

Eighty seven cases of Ménière's disease were examined for clinical evidence of deficiencies of the vitamin B group. These deficiencies were correlated with the type of vertigo and the character of the response to histamine given intradermally.

The following conclusions were drawn:

1. The patients who experience rotational vertigo alone show signs of nicotinic acid deficiency; they give a small response to histamine, and can be relieved of their attack with nicotinic acid.

2. The patients with positional vertigo alone, described as momentary dizziness on sudden movements of the head, or as longer periods of general unsteadiness, have riboflavin deficiency symptoms; they give a strong response to histamine, and are relieved by the administration of riboflavin.

3. The patients who have both types of vertigo show signs of deficiency of both vitamins; five are

intermediate response to histamine, and respond only when both nicotinic acid and riboflavin are given
JOHN R. LINDSAY, M D

Surgery of Chronically Discharging Ear HOWARD P HOUSE *Arch Otolaryngol*, Chic., 1949, 49 135

The author describes several important anatomic landmarks and surgical maneuvers in endaural temporal bone surgery for chronically discharging ear

A perforating burr is used to enter the antrum. The point of entrance is such that an imaginary line drawn directly posterior from the superior margin of the external bony ear canal will cross the upper margin of the completed perforating burr hole. A line drawn directly superior from the posterior margin of the bony external ear canal will cross the anterior margin of the completed perforating burr hole. This burr hole should never be deeper than the cutting portion of the burr.

In the simple mastoidectomy, after the posterior bony ear canal wall has been thinned, the dural plate exposed, and the horizontal canal identified, a small burr is used to remove the zygomatic cells. The removal of these cells exposes a thin shelf of bone which forms the external wall of the epitympanum.

The modified radical mastoidectomy is a continuation of this procedure. The thin bone shelf overlying the epitympanum is removed and the short crus of the incus and the neck and head of the malleus are exposed. The posterosuperior bony ear canal wall is then taken down. The narrow Lempert elevator is used to separate the membranous canal wall from the bony bridge which is then removed with the rongeur. Pathologic tissue is removed from the epitympanic area. If there has been necrosis in the ossicular chain, the incus and the head and neck of the malleus are removed. A flap may be created as in the fenestration operation. If the epitympanic pathologic tissue has been satisfactorily removed the skin flap is not created and the cavity is allowed to heal as in a simple mastoidectomy. The attic perforation usually closes spontaneously.

In the radical mastoidectomy all remnants of the incus and malleus are removed. A skin flap may be created or completely removed. When the skin flap is preserved, an additional graft may be acquired from the postauricular area and when used seems to expedite healing of the cavity. Before granulations are removed from the middle ear the fallopian canal must be brought into view to avoid injury to the facial nerve. This is accomplished by carefully elevating the periosteum over the horizontal canal until its anterior extremity is reached. The dull ring curette is then directed over the processus cochleariformis into the middle ear. The processus cochleariformis is fractured externally and the tensor tympani muscle and all accessible pathologic tissue in the middle ear are removed.

Granulations over the stapes area can be more safely removed if one uses a posterior to anterior maneuver, which takes advantage of the counterpull of the stapedius tendon. JOHN R. LINDSAY, M.D.

Lempert Endaural Subcortical Mastoidotomy for the Cure of Chronic Persistent Suppurative Otitis Media JULIUS LEMPERT *Arch Otolaryngol*, Chic., 1949, 49 20

The chief complaint of almost every patient suffering from chronic otitis media without intracranial complications, for whom mastoidotomy is indicated and advocated by his otologist, is, as a rule, the annoying discomfort of the persistence of his long-standing middle ear discharge, the arrest of which has resisted all available medicinal therapy.

Both the unwillingness of the otologist to assure the patient reasonably of a permanently dry middle ear and his volunteering the information that intracranial extension of the infection will thus be prevented are, as a rule, based on his own experience with mastoidotomy without any attempt on his part to analyze and determine the causes which make such inconsistent facts possible.

The prevention of intracranial extension of the infection is naturally governed by the same surgical factors in the performance of mastoidotomy which govern the arrest of the suppurative discharge, namely, the complete extirpation of the foci of infection. Therefore, it is inconsistent for an otologist to give hope for the prevention of extension of the infection in the face of his lack of confidence regarding his ability to arrest the discharge.

The traditionally accepted and most commonly employed technique of mastoidotomy, known as the Schwartze postauricular radical mastoidectomy, is not conducive to, and does not encourage, the average otologist either to explore successfully, or to eradicate completely by surgery when explored, the varied and multiple pathologic processes which may be encountered. Only after a large experience with this technique can the especially skilled otologist cope successfully with the commonly encountered small sclerotic mastoid process and perform a complete mastoidotomy, and then not always without accident.

The average otologist, when performing the Schwartze radical mastoidectomy, does not in the majority of instances remove completely the pathologic process responsible for the middle ear discharge. The inadequate performance of the Schwartze postauricular radical mastoidectomy is usually prompted by the surgeon's fear of injuring instrumentally one or more of the many vital anatomic structures which may be encountered blindly.

The adjective "radical" when applied to the Schwartze technique is therefore an exaggeration, for the way it is practiced by the average otologist makes the adjective "incomplete" more appropriate and more explanatory.

It is a well established fact today that mastoidotomy can be performed through endaural incisions alone without a supplementary postauricular incision. The postauricular incision is therefore not only unnecessary but also nonsurgical in principle since it involves a sacrifice of soft tissue greater than necessary for accomplishing the desired result.

The technique is fully described and illustrated with 13 drawings

Certain advantages are claimed for the endaural method, such as eliminating the blind search for the antrum by directing all the instrumentation away from the vital structures toward the operation with no danger of a postauricular fistula

Any well trained otologist of average skill, though young in experience, can successfully perform the endaural subcortical mastoidotomy with- out being handicapped by the mental hazards which prevent him from performing the Schwartze radical mastoidectomy successfully

JOHN F. DELPH, M.D.

Reconstruction of the Auricle with Diced Cartilage Grafts in a Vitallium Ear Mold LYNDON A. PEER. *Plast Reconstr Surg*, 1948, 3 653

This article is profusely illustrated with 24 photographs and drawings, all with descriptive texts. Essentially, the technique of reconstructing the auricle consists of exposing the ear cartilage and burying it beneath the skin and during the same operation an ear mold filled with diced cartilage is inserted in an abdominal pocket. Five months later the cartilaginous framework is removed from the mold, and the upper part of the framework, which corresponds to the ear defect, is buried in the skin in the exact location of the defect. An Esser inlay is used to cover the back of the framework and raw scalp surface.

Whenever possible the first operative step to reconstruct an auricle should begin when the child is about 4 years old. This allows the surgeon a sufficient time interval in which to complete the ear before the child enters school, which lessens his handicap and facilitates adjustment with his schoolmates.

Autogenous cartilage is always the material of choice for transplantation. It survives as living tissue, is not subject to invasion or absorption, and, like an autogenous skin graft, it remains until the individual in whom it is transplanted dies. This is true whether the cartilage is transplanted with or without its perichondrium.

Preserved cadaver grafts are invaded by fibrous tissue usually over long periods of time, but occasionally they are absorbed rather suddenly. Therefore, preserved cadaver cartilage is not good grafting material to support an ear in a young child with a possible 60 year life expectancy.

Dupertuis demonstrated the growth of costal cartilage grafts in rabbits, and the author's own experimental studies with young human costal cartilage grafts indicated that there was a small increase in the size of the graft in most cases. It should be emphasized, however, that the growth possibilities in an ear framework constructed of multiple segments of young costal cartilage grafts are not known.

From a clinical standpoint, at this time, the author forms the reconstructed ear slightly larger than the normal ear and plans to make any necessary adjustments when and if they are necessary.

JOHN F. DELPH, M.D.

Modified Radical Mastoidectomy. Preservation of the Cholesteatoma Matrix, a Method of Making a Flap in the Endaural Technique SHIRLEY HAROLD BARON. *Arch Otolaryngol*, Chic, 1949, 49 280.

The somewhat confused literature on chronic otorrhea and its therapy is reviewed. The pathology and pathogenesis divide chronic otorrhea into a benign type with central perforation and mucoid discharge, and a dangerous type in which cholesteatoma is present. Cholesteatomas are squamous epithelial lined cysts filled with epidermoid debris and its decompensation products. They are subdivided into true cholesteatomas and pseudocholesteatomas, which are pathologically identical. True cholesteatomas (better called *congenital cholesteatomas*) are not associated with the ear. They are due to the rather rare congenital epithelial rests occurring anywhere in the skull. Pseudocholesteatomas (better called *acquired cholesteatomas*) are due to a process which takes place after birth. They are differentiated into primary acquired cholesteatomas, in which there is no previous acute suppurative process, and secondarily acquired cholesteatomas, which are secondary to an acute necrotic middle ear infection. This infection destroys not only all of the mucous membrane of the middle ear but all or at least a marginal portion of the drum and allows healing to take place by an ingrowth of squamous epithelium into the middle ear. This results in a cholesteatomatous cyst or sac of which the neck is connected to a marginal perforation in the tympanic membrane. The primarily acquired cholesteatoma is an epithelium lined cholesteatomatous sac of which the neck is connected to a perforation in the Shrapnell membrane. This type is secondary to a chronically obstructed eustachian tube with retraction of Shrapnell's membrane or to infantile otitis.

The author believes that cholesteatomas cannot be cared for safely by conservative therapy such as attic irrigations, at least not in most cases. She also believes that in almost all cases cholesteatomas can be cared for by the modified radical operation which has the great advantage that no further damage is done to the conductive mechanism of the middle ear, so that hearing is preserved and sometimes actually increased as the ear becomes dry. The modified radical operation should be done in all cases in which the lateral half of the cholesteatomatous sac can be exposed without injury or destruction of any vital portion of the middle ear conduction mechanism. In most cases this means attic cholesteatomas in which the outer attic wall can be taken down to expose the cholesteatomatous sac. The outer half of this sac and the outer half of the neck of the sac are removed. The previously elevated skin of the superior canal wall is slit longitudinally to communicate with the neck of the sac and then is laid backward to provide a plastic skin graft to help line the new addition to the canal wall. This procedure incorporates the attic portion of the tympanic cavity and the excavated outer attic wall into the bony canal wall. The inner portion of the cholesteatomatous sac is left as it helps to

epithelize the cavity. The outer portion of the meatal skin flap is then laid anteriorly to help epithelize the anterior canal wall.

In cases in which complete exposure of the cholesteatoma requires removal of the ear drum and other hearing structures, a radical mastoidectomy must be done. Postauricular incision may be used but the endaural approach is much more satisfactory.

WILLIAM K. WRIGHT, M.D.

NOSE AND SINUSES

The Role of the Septum in Rhinoplasty JACQUES W. MALINIAC *Arch Otolaryngol*, 1948, 48:189

The author attempts to elucidate the supporting function of the septal, triangular (upper lateral), and quadrangular (alar or lower lateral) cartilages of the nose. He believes a rhomboid "weak spot" in the cartilaginous framework is present at the junction of the upper and lower lateral cartilages anteriorly and is a likely spot for a depression deformity of the nasal profile in the event of an excessive removal of the nasal septum. The alar dome, he alleges, "is suspended by the upper lateral cartilages from above and supported by the lower lateral cartilages from below."

Suggestions as to technique are made for three types of septal deformities: (1) septal deflection with oversized hump deformity, (2) crushed septal fracture with depressed external deformity, and (3) septal deflection with external lateral deflection. "As a general rule, if the deflection is such as to interfere with the successful performance of corrective rhinoplasty, it should be repaired simultaneously with, or prior to, the latter."

JOHN J. BALLENGER, M.D.

Potential Hazards from Radiation Treatment of Hypertrophied Lymphoid Tissue in the Nasopharynx LAURENCE L. ROBBINS and MILFORD D. SCHULZ *Laryngoscope*, 1949, 59:147

A warning is issued of the possible dangers in the use of the radium applicator in treating hypertrophied lymphoid tissue of the nasopharynx.

Latent radiation necrosis has been seen from 10 to 20 years after treatment of benign lesions of the skin. The radiation dosage in some of these cases was approximately the same as that now recommended for use in the nasopharynx for the reduction of hypertrophied lymphoid tissue.

The following suggestions are made:

1. The use of radium treatment with the monel metal applicator should not be routine.

2. Except in selected cases the treatment, when given, should consist of no more than an erythema dose.

3. The erythema dose should be determined individually for each applicator and, if any other means of determining the proper dose for a particular applicator fails, the dose may be estimated by trial on the operator's skin.

JOHN R. LINDSAY, M.D.

MOUTH

Chemosurgical Treatment of Tumors of the Parotid Gland FREDERIC E. MOHS *Ann Surg*, 1949, 129:381

The main object of parotid tumor surgery is (1) the complete removal of the neoplasm, and (2) the preservation of as much of the facial nerve as possible.

After premedication with morphine sulfate (0.015 gm) a keratolytic, dichloroacetic acid is applied to the portion of tumor covered by skin. Whitening of the skin indicates that the keratin layer has been rendered permeable to the zinc chloride. The latter is applied as a paste about 3 mm thick; it contains 40 gm of stibnite (80 mesh sieve), 10 gm of powdered sanguinaria, and 34.5 cc of a saturated solution of zinc chloride. The treated area is covered with a thin layer of cotton and then a second layer of cotton with petrolatum to get a moisture tight closure.

After 24 hours a layer of tissue about 1 cm thick is excised, if there is doubt about the extent of neoplastic involvement frozen sections are made. As a rule, there is no pain and no bleeding because the incision is made through killed and fixed tissue. Following the excision the fixative is reapplied, and the procedure is repeated after 24 hours. After several days it is usually impossible to differentiate grossly normal from cancerous tissue. Therefore frozen sections are made and the areas of cancer are marked with red pencil on a corresponding map, the latter corresponding to an area marked on the lesion with merbromin. The fixative is then reapplied to the involved area. This process is repeated for several days until all involved areas are gradually excised.

In some areas the neoplasm extends more than 2 cm beyond the grossly visible tumor, it may follow the perineural lymphatics of the facial nerve or the perimysium of the stylohyoid muscle. Without systematic microscopic control these extensions would have been missed.

The treatment of 17 patients is reported. A case of an 80 year old patient is described; he was treated for a parotid squamous cell carcinoma, grade 3, measuring 6.5 by 8 cm and with a central ulceration. The procedure lasted for 20 days, and the defect was healed 2 months later with paralysis of only the mandibular branch of the facial nerve.

In younger patients a prophylactic or therapeutic neck dissection is recommended, also a carotid ligation before treatment is at times advisable in order to avoid hemorrhage, which occurred in 4 of 17 cases and required a suture-ligature or pressure dressing. Ligation of the external carotid artery was performed, once prior to therapy because of obvious deep extension, and a second time because extension around the external carotid was found. Salivary fistulas lasting from 1 week to 21 months were encountered in 15 of the 17 cases reported. Only 4 fistulas persisted over 4 months. Fistulas may be

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS, CRANIAL NERVES

Thorotrast Pyograms in Cerebral Abscess G K TUTTON and W H T SHEPHERD *Brit J Surg*, 1949, 36 240

Although the value of thorotrast visualization of intracranial abscesses has been well recognized, there has been comparatively little written about their detailed appearance and its implications. The authors report their study of 56 cases of intracranial abscesses in which thorotrast visualization (pyograms) had been carried out. Thirty-eight of the abscesses were due to a direct spread of otogenous origin, paranasal sinusitis, or osteomyelitis of the vault, there were 6 deaths in this group. Seven cases were post-traumatic with 2 deaths. Nine cases were metastatic with 7 deaths, and 2 were of postoperative infection with 1 death. Hence, among the 56 cases there were 16 deaths.

The usual routine in the treatment of a brain abscess is a needle exploration for the abscess through a burr hole. When the cannula is within the abscess cavity its position is maintained and pus is permitted to escape spontaneously. Gentle aspiration is then performed, after which "a mixture of the appropriate antibiotic and 2 c.c. of thorotrast are injected through the cannula." If air is not spontaneously sucked into the cavity, about 2 c.c. are injected, after which the needle is withdrawn and the incision is closed.

A standard roentgenologic technique is advocated in order to permit accurate comparisons with future films. Besides the more routine positions of skull studies, a lateral film in the brow up and brow down position is particularly important. Usually repeat studies are made 4 days after the initial injection, or earlier if necessary, and thereafter at weekly intervals. If the pyograms reveal an insufficient amount of thorotrast, a second injection is made. The initial roentgenograms reveal the thorotrast as an ill-defined shadow, irregular in outline and density. The abscess capsule is usually not visualized until between the sixth and thirty-fifth days after injection in the more acute abscesses which have been present less than 28 days. In abscesses of 30 days or older, the capsule is usually seen within 4 days.

The course of the abscess can be followed in the late stages by the roentgenologic changes of the capsular shadow. Cases in which the head has not been moved about freely or in which a small amount of thorotrast has been injected reveal only a part of the capsule to be well visualized. This would be the most dependent portion. Initially the shadow is spherical, ovoid, or loculated. After resolution of the abscess either by repeated aspirations or a natural process, the capsule becomes thickened and crinkled. If the outline becomes smoother and more

spherical, it indicates that the abscess is enlarging. This is a most important point, since the clinical signs may be very late in appearing.

An important finding by the authors is that the presence of tracts, communications, or pointing of the capsule may suggest the origin of the infection. With shrinkage or contraction there is usually a migration toward the site of origin or attachment which may not have been obvious in the initial pyogram.

Loculation was present in almost half of the cases. Twelve were recognized in the first pyogram and 9 were recognized either at later studies or in retrospect. In 2 cases of verified loculation, the pyograms were negative. Loculation was most easily demonstrated in temporal and cerebellar abscesses.

Four cases of associated intracerebral and subdural abscess were observed in this series. Subdural abscesses on the medial or inferior surfaces of the hemisphere can be definitely recognized only by pyography since it can be tapped only by passing through the cerebral substance.

The progress of the capsule formation is the most definitive indication for surgical excision since both the age of the abscess and the thickness of the capsule can be formulated. In the present series the average thickness of the capsule at time of surgical removal was 2.7 mm and the average age was 76 days. The abscess was usually extirpated through an osteoplastic flap unless it was felt that to do so would cause irreparable functional damage.

JACK I. WOOLF, M.D.

Abscess of the Frontal Lobe Secondary to Ethmoiditis JOSEPH H. KLER *Arch. Otolaryngol.*, Chic., 1949, 49 125

The author discusses 3 cases of ethmoiditis which were complicated by single encapsulated frontal lobe abscesses. They presented signs of increased intracranial pressure, meningeal irritation, and periorbital swelling.

Chronic infection of the ethmoid cells is more likely to develop into cerebral abscess than acute infection. The infection passes by continuity through the bone and the meninges, or extends by way of thrombophlebitis of the veins communicating with the dura.

Chemotherapy and adequate draining of the local infection and its intracranial and intracerebral extension is the treatment recommended.

GEORGE PERRET, M.D.

Rathke's Cleft and Its Cysts M. L. BAYOUMT *Edinburgh M. J.*, 1948, 55 745

This article deals with the incidence and histology of Rathke's cleft and its cysts and is based on a study of 200 pituitary glands that were collected from autopsy cases of the Neuropathology Department, Royal Infirmary, Edinburgh. As a routine

procedure, the glands were divided sagittally into two halves. Fixation was carried out in Hellv's fluid, formalin, or alcohol. Frozen sections were cut when necessary. The rest of the glands were embedded in paraffin. Serial sections were cut at 6 micra. Two sections were mounted at every one hundred and sixty-sixth cutting. One section was stained with hematoxylin eosin and the other kept for further use. Sudan III and Mayer's mucicarmine stains were used to demonstrate fat and mucin, respectively.

The author noted a distended cleft separating the anterior lobe from the rest of the gland through the whole length of the sagittal plane in 26 of 200 cases (13 per cent).

With regard to the structure of Rathke's cleft cysts, the cyst is lined in parts by tall columnar mucus-secreting epithelial cells possessing numerous delicate cilia. The nuclei are small, rounded, and deeply stained, and lie at the bases of the cells. The ciliated epithelial cells are especially noticeable at the upper and posterior part of the cyst wall. They are invariably visible on serial sectioning. In other parts of the cyst wall, the epithelial lining has become compressed, flattened, and has lost its cilia. The cysts usually contain one or more of the following elements:

- 1 Large foam cells with granular swollen cytoplasm and pyknotic excentric nuclei. Fat stains are negative, while the mucicarmine is positive, which indicates that the cells are derived from degenerating desquamated epithelium.

- 2 Cholesterol crystals

- 3 Mucinous material and granular debris with remains of disintegrated pyknotic nuclei.

Rathke's cleft cysts may enlarge to such an extent as to give rise to symptoms. Clinically, they are identical with the hypophysial duct tumors (craniopharyngioma) arising from the lower group of epithelial rests at the root of the stalk. Histologically, these cysts form a separate entity from the epidermoid tumors.

The differentiation of Rathke's cleft tumors from other congenital neoplasms of the hypophysis on histogenetic evidence is discussed and verified.

HOWARD H. LANDER, M D

Tuberous Sclerosis with Cerebral Neoplasm J C PARR *N Zealand M J*, 1948, 47 550

Tuberous sclerosis is an uncommon hereditary disease usually manifesting itself in infancy or early childhood and is characterized by defective mentality, progressive epilepsy, and a facial rash called adenoma sebaceum. The latter is a reddish or skin-colored papulelike growth distributed in "butterfly" fashion over the face. Occasionally associated retinal tumors are found. Although no symptoms may have resulted from their presence, autopsy often reveals affection of other organs, such as hypernephromas and cardiac rhabdomyomas.

The authors presented a case report of a 43 year old male who had been a successful farmer until

recently when he had a sudden change in mentality and personality. Past history revealed that he had convulsions as a baby, and a rash on his face had been present since boyhood. His mother, who had always enjoyed good health, had a similar rash. Funduscopic examination revealed numerous pearly white nodules in the retina and papilledema. Ventriculography was done. The third ventricle was filled only in its upper portion and displaced to the right. The left lateral ventricle was displaced upward. The lateral ventricles were enlarged and a space-occupying lesion in the thalamus on the left was suggested. Treatment consisted of ventriculocysternostomy followed by deep x-ray therapy. Thereafter, his papilledema subsided and his condition was improved generally, but he remained slow and listless.

DANIEL RUGE, M D

Massive Intraventricular Epidermoid Review of the Literature and Report of a Case HOWARD W. DUEKER and J. M. A. SANCHEZ-PEREZ *Bull Los Angeles Neur Soc*, 1948, 13 220

Another case is added to reports in the literature of approximately 200 intracranial epidermoids. The authors review the case of a male, 47 years of age, who complained of unusual fatigue and nervousness of 10 years' duration. For 20 years the patient had occasional generalized convulsive seizures accompanied by unconsciousness. Physical examination revealed left homonymous hemianopia, minimal left spastic hemiparesis, and mental confusion. Electroencephalography, pneumoencephalography, cerebral angiography, spinal fluid examination, and ventriculography were done and showed abnormalities compatible with a space-occupying lesion on the right side. An osteoplastic flap was turned in the parietal region but the tumor was not located. The patient expired on the first postoperative day. Post-mortem examination revealed a tumor, 7.1 cm by 4.3 cm, occupying the posterior half of the right lateral ventricle.

According to the authors the ventriculograms and, to a lesser extent, the angiograms and the electroencephalogram served, in retrospect, to accurately outline this epidermoid tumor. Ventriculograms and photographs of the coronal sections of the brain containing the specimen are reproduced.

The review of the literature is very brief, the majority of the paper being devoted to the case history, laboratory findings, and postmortem examination of the brain.

JOHN L. BELL, M D

Fetal Cell Adenomas of the Hypophysis Cerebri M. L. BAYOUNT *Edinburgh M J*, 1948, 55 750

A study of the adenomas of the human hypophysis and their classification on a histogenetic basis reveals a group of tumors arising from embryonic cells. These neoplasms form a special entity with a characteristic morphological picture.

The material studied consisted of two groups. The first group comprised 105 cases of hypophysial chromophobe adenomas removed surgically.

suture less subject to tension. In 16 of these a portion of the clavicle was resected.

The experience at the Center with this resection has been that in cases of extensive destruction of all or a great part of the elements of the brachial plexus, such as those with complicating fracture and osteomyelitis, in which the resultant cicatricial development has been excessive, the better exposure of the field of operation will shorten the time of operation materially. In some cases of short-necked and fat individuals proper exposure cannot be obtained without it. In the cases of interruption of the seventh and eighth cervical and first dorsal roots the necessary suture would be impossible without approaching the shoulder to the trunk.

The simple cutting through of the clavicle, even when placed toward the inner or outer end of this bone, will, as a rule, result in overriding and the development of abundant callus which will bring the menace of later pressure on the plexus.

The clavicle is a rudimentary bone and its functioning will be taken over satisfactorily by the associated musculoligamentous complex of the shoulder. The absence of the clavicular bone will not leave any particular deformity or false posture of the arm. There may possibly remain a slight lowering of the shoulder in comparison with the other side and a slight narrowing, but these will not noticeably show through the ordinary clothing.

Six photographs are appended, showing the insignificant character of the resultant deformity from 2 to 5 years after the operation. Some of these illustrate a regaining of function in the extremity supplied by the injured plexus, which suggests an actual advantage gained by the procedure.

JOHN W. BRENNAN, M.D.

Traction Injuries of the Brachial Plexus in Adults

ROLAND BARNES *J. Bone Surg.*, 1949, 31-B, 10

The author presents a review of 63 cases of closed injuries of the brachial plexus in patients who were treated in British peripheral nerve injury centers during the war. Most of these traction injuries occurred as the result of motorcycle accidents, in which forcible separation of the head and shoulder was the main factor. Thirteen injuries were classed as non-degenerative lesions. In degenerative lesions the pattern of recovery was fairly constant, lesions of the three upper roots recovered well, and lesions of the entire plexus did not completely recover.

Rupture of nerve roots with complete separation of the torn ends occurred only rarely in this series, as verified by operative exploration. The main damage to the plexus was intraneural. When rupture of nerves was encountered, it was impossible to perform satisfactory end-to-end suture after adequate resection of the scarred stumps. Horner's syndrome is considered a grave prognostic sign indicating irreparable injury of the lower roots and often of the entire plexus.

The author advocates conservative, nonoperative treatment for this type of injury of the plexus. Be-

cause the chief barrier to regeneration was found to be intraneural scarring, early or late explorative operation was not deemed justifiable except for the relief of pain in selected instances. According to the author, reconstructive procedures to improve the function of the limb after the extent of recovery has been established should not be considered earlier than 15 months after injury. An extensive routine of physical therapy is advocated for patients with traction injuries of the brachial plexus.

JOHN L. BELL, M.D.

Late Spinal Paralysis after Avulsion of the Brachial Plexus

WILDER PENFIELD *J. Bone Surg.*, 1949, 31-B, 40

This unusual case presentation is that of a man who, as a boy, suffered a severe traction-avulsion injury of the brachial plexus, during which accident the extremity was completely avulsed. The patient recovered without any immediate spinal cord paralysis, and lived to die of cardiac disease at the age of 65.

In early adult life he began to show some evidence of cord involvement, mainly on the right side (the side of his injury), and he had evidence of cervical autonomic involvement on this side. He was subjected to a laminectomy at the age of 60, and it was found that the cord was angulated sharply and pulled out into the first thoracic intervertebral foramen on the right. It was believed that not only had the original injury pulled the cord over, because of traction on the root, but that the cord had, by the gradual process of scar formation, been pulled slowly into this enlarged foramen.

The right first thoracic nerve was cut across, and the cord moved back toward the midline of the vertebral canal into its normal position. The cord was, surprisingly enough, found not to be particularly atrophied, even after being out of its proper position for such a long time in the presence of surrounding scar tissue.

JOHN MARTIN, M.D.

Treatment of Residual Paralysis—Brachial Plexus Injuries

A. M. HENDRY *J. Bone Surg.*, 1949, 31-B, 42

In the present article the author makes a plea for the preservation of the patient's own upper extremity after severe paralysis following brachial plexus injury, rather than the use of amputation and an artificial limb.

The important point is made that even though the patient requests amputation of the apparently useless extremity, he should be prevailed upon to try less radical methods to preserve his arm by such reconstructive surgery as might be suited to his case.

The author has considered the severe paralysis following brachial plexus injury according to the functional levels of the extremity—that is, the hand, wrist, forearm, elbow, and shoulder—and case reports are given to illustrate his approach to the problem in the various levels. He feels that when nerve repair is impossible, the transposition of muscles which are still functioning or likely to regain func-

tion must be carefully considered and worked with. Very frequently a well chosen arthrodesis will place the extremity, or part of it, in at least a semifunctioning position. He points out that even a flail-like hand can thus be placed into some semblance of a functional position, and that an elbow which hangs fully extended causes incapacity of the extremity. Again, transposition of the proper muscles or the placement of a bone-block behind the elbow, permitting initial flexion, will greatly improve the weight-carrying angle. It is believed that arthrodesis of the shoulder joint should be the last treatment of a paralyzed upper limb, however, when indicated, arthrodesis of the shoulder may add greatly to the rehabilitation of the extremity.

JOHN MARTIN, M D

An Operative Approach to Supraclavicular Plexus Injuries J E BATEMAN *J Bone Surg*, 1949, 31-B 34

In the treatment of 21 patients requiring supraclavicular exploration of the brachial plexus following injury, the author's operative approach was different from the classical supine position. He advocates the sitting position with the head rotated away from the injured side and the shoulder in the dependent position.

The procedure is as follows:

A vertical incision is made, extending from the midpoint of the lateral border of the sternocleidomastoid to the middle third of the clavicle, the external jugular vein is ligated, following retraction of the sternocleidomastoid, the omohyoid muscle is divided, the suprascapular and transverse cervical vessels are ligated, following which the brachial plexus is exposed. Although seldom necessary in the present series, further exposure may be attained by division and retraction of the clavicle. As the clavicle is pulled down by the dependent shoulder, it is possible to explore a larger field from above, and the structures of the plexus remain more superficial than when the supine position is employed.

JOHN L BELL, M D

The Surgical Routes in High Lesions of the Sciatic Nerve (Le vie chirurgiche nelle lesioni alte dello sciatico) G MORANDI *Chir org movim*, 1948, 32 383

Basically, four routes have been proposed to expose the anatomic lesion of the high portion of the sciatic nerve:

1 A longitudinal incision perpendicular to the course of the nerve from its origin to the upper third of the thigh, also called Foerster's longitudinal incision on the median line. It involves the skin, subcutaneous tissue, aponeuroses, gluteus maximus, and origin of the femoral biceps muscle, and provides good visibility of the nerve, but forces the surgeon to operate on a deep plane which, especially in obese subjects, makes the surgical manipulations of the nerve difficult.

2 Iselin's incision follows the lateral border of the gluteus maximus from the iliac crest down and

runs for a few centimeters on the median line between the great trochanter and the ischiatic tuberosity. It cuts the skin, subcutaneous tissue, and aponeurotic fascia, and detaches the insertion of the gluteus maximus or, if the lesion is very high, respects the lower two-thirds of the insertion. Medial retraction of the flap exposes the sciatic nerve from the piriform muscle to the femoral biceps.

3 The incision of Toennis begins at the level of the posterosuperior iliac spine and runs along the medial border of the buttock to the intergluteal sulcus in the form of a reversed question mark to join the median line between the great trochanter and the ischiatic tuberosity, from where it descends on the thigh for a few centimeters. It cuts the skin, subcutaneous tissue, part of the upper insertion, and then the muscular tissue of the gluteus maximus lower down. Lateral retraction of the flap exposes the apparent origin of the sciatic nerve down to the gluteal fold, and removal of part of the sacral ala exposes the roots of the nerve.

4 The oblique incision following the course of the fibers of the gluteus maximus begins at the level of the great trochanter and allows separation of the muscle bundles to reach the sciatic nerve which crosses the operative field. It exposes only a small portion of the nerve and is impractical because the surgeon has to work in a deep groove in which vision is poor.

On the basis of 58 firearm lesions of the sciatic nerve involving the portion between its apparent origin and the upper third of the thigh, which were operated upon, the author draws the following conclusions:

In lesions at the limit or immediately below the lower bundles of the gluteus maximus, the median incision at the upper third of the thigh associated with partial section of the lower muscular bundles of the gluteus is indicated. When the lesion is between the apparent origin of the nerve and the lower limit of the gluteal mass, Iselin's incision with distal detachment of the gluteus maximus is used. In lesions involving the roots of the nerve, the Toennis incision with removal of part of the sacral and iliac ala is indicated. In all cases in which the gluteus has been detached proximally (Toennis) or distally (Iselin) or cut in the median line, the region must be put at rest by the use of a hip plaster cast which is removed after 30 days unless the nature of the operation on the nerve (suture) requires 45 days, this will allow the formation of a solid scar for the gluteal muscle and a return to normal conditions.

RICHARD KEMEL, M D

MISCELLANEOUS

Preoperative and Postoperative Care in Neurosurgery (Cuidados preoperatorios y postoperatorios, en neurocirugía) RAMÓN DEL CUETO, JR *Asa* 1949, No 29 1912

With the exception of the surgery of the heart, blood vessels, and lungs, there is no field of surgery

concluded that until a further examination of this material can be carried out in 5 years' time, the supraclavicular glands should be removed with the axillary group of glands when the latter are seen to be macroscopically invaded. In contradistinction, the authors state that removal of supraclavicular glands is not necessary in the absence of any axillary glandular involvement.

In 2 previous series of investigations, practically speaking, the same incidence of recurrence in the supraclavicular glands was found as in this present series, in which microscopic metastases were found after the preventive removal.

The great question to decide is whether microscopic metastases of the supraclavicular glands should be judged in the same light as clinically established supraclavicular glandular involvement, that is to say that the case is inoperable and that consequently the removal of the supraclavicular group of glands is unnecessary. This question will be answered by subsequent examinations.

TRACHEA, LUNGS, AND PLEURA

Practical Correlative Anatomy of the Bronchial Tree and Lungs JOHN FRANKLIN HUBER *J Natl M Ass*, 1949, 41: 49

The lung, in its ultimate analysis, is the total branching of the bronchus leading to the lung. As the main bronchus gives off a branch going to a lobe, the lobe can be considered as the total branching of the bronchus going to it. Each branch of the bronchus entering a lobe divides to form a definite portion of that lobe. Thus, there are three branches of the right upper lobe bronchus, and the total branching of each of these branches forms a definite portion of the right upper lobe, so that the right upper lobe is divided into three parts on the basis of the bronchial distribution. The name bronchopulmonary segment is commonly used for the portion of lung substance which is the total branching of a bronchus.

Based on this concept, the lungs may be divided into the following segments:

Right lung		Left lung	
Lobes	Segments	Lobes	Segments
Upper	Apical	Upper	Upper { Apical posterior
	Posterior		division { Anterior
Middle	Anterior	Lower	Lower { Superior
	Lateral		lingular { Inferior
Lower	Medial	Lower	division { Superior
	Superior		{ Anterior medial
	Medial basal		{ basal
	Anterior basal		{ Lateral basal
	Lateral basal		{ Posterior basal
	Posterior basal		

The subdivisions of the lung having thus been named, the bronchus is named according to the subdivision of the lung to which it goes.

This concept of bronchial branching and related subdivision of the lung is of clinical importance. A bronchoscopist is immediately able to relate the bron-

chial orifice he sees to a definite portion of the lung. The radiologist can more specifically locate the abnormality he finds. The thoracic surgeon can do a segmental resection rather than a lobectomy.

The question of the predilection of disease for certain segments requires much study. Thus, the posterior segment of the upper lobe is a favorite for tuberculosis. Lung abscess is apt to appear in the superior segment of the lower lobe or in adjacent parts of the anterior and posterior segments of the upper lobe. Bronchiectasis commonly involves the lower lobe, the adjacent part of the middle lobe on the right side, and the lower or lingular division of the upper lobe on the left. Pneumonia may have a slight predilection for the superior segment of the lower lobe.

SAMUEL KAHN, M D

Bronchostenosis of Inflammatory Origin, with a Report of 6 Cases H F FABRITIUS AND H ØDE GAARD *Acta radiol*, Stockh., 1948, 30: 385

Bronchial obstruction is believed to be the commonest cause of atelectasis. Obstruction of the lumen, changes in the bronchial wall, or extrabronchial compression may occur. The changes in the bronchial wall may be inflammatory or neoplastic. In the present article the authors deal with obstruction due to inflammation.

Six cases of bronchial stenosis with associated peripheral changes in the lung are reported. In all of these patients the stricture was caused by local inflammation. The condition was verified by roentgenography and bronchoscopy in each case. All patients gave a history of prolonged bronchial symptoms. In 1 case the inflammation originated around a foreign body, in 2 cases the tuberculous bacillus was demonstrated, but after extirpation no evidence of tuberculosis was found. The author points out that chronic bronchitis may mask a bronchostenosis caused by localized inflammation in a bronchus.

ROBERT E FLORER, M D

A Case of Arteriovenous Aneurysm of the Lung Cured by Resection OLAF BRØBECK *Acta radiol*, Stockh., 1948, 30: 371

The clinical characteristics of arteriovenous aneurysm of the lung are cyanosis, polycythemia, clubbing of fingers, and x-ray findings. Other clinical findings are dyspnea and fatigue, small hemangiomas of the skin, and a murmur over the aneurysm. In this condition some blood passes through the pulmonary circulation without having been oxygenated. On x-ray examination, a small or large rounded shadow is seen in the lung field and sometimes pulsation may be observed by fluoroscopy. A more characteristic finding is that the shadow is connected with the hilar region by broad sinuous densities. A case is presented of a 34 year old woman with a history of cyanosis and dyspnea since childhood. She was poorly nourished, there were many superficial angiomas on the face, there was stasis of the veins of the neck and brow, and clubbing of the fingers. On x-ray examination, a dense, well defined shadow was ob-

Fig 1 (J F Huber) The tracheobronchial branching as far as the "segmental" bronchi correlated with the subdivision of the lungs on the basis of bronchial distribution. The terminology used is that suggested by Jackson and Huber. Because of insufficient space the word "segment" was omitted in each case from the labelling of the segments. The symbols in each bronchus indicate which segment it branches out to form. Each bronchial branch should be designated by the name of the subdivision of the lung supplied by it.

ved in the left lower lung field near the cardiac shadow. Pulsation of the tumor could not be demonstrated by fluoroscopy.

On thoracic exploration it was found that anterior in the lower lobe there was apparently a sac the size of a large walnut which was so thin-walled that

the blood could be seen passing through it. This sac was seen to be connected with the lingula where it continued in a much larger thin-walled sac. The sac entered the inferior pulmonary vein. The aneurysm was resected. The postoperative course was uneventful.

ROBERT E. FLORER, M.D.

Streptomycin as an Adjunct in the Surgical Treatment of Pulmonary Tuberculosis DANIEL A. MULVIHILL, LAURENCE MISCALL, ROBERT KLOPSTOCK, and JOSEPH BITSACK *J Thorac Surg*, 1949, 18 1

The authors' experience with streptomycin as an adjunct in the surgical treatment of pulmonary tuberculosis in the Triboro Hospital, Jamaica, Long Island, during the year 1947 is presented. The results in 65 cases of pulmonary, pleural, and chest-wall tuberculosis treated with streptomycin are summarized, and case histories typical of each group are cited. Twenty additional thoracoplasty patients who had not received streptomycin are included as controls. The efficacy of preoperative and postoperative streptomycin treatment in the prevention of postoperative complications in pulmonary resection for tuberculosis and thoracoplasty is evident. Beneficial effects of topical application of the drug in combination with open operations for bronchopleural fistulas and residual tuberculous empyema spaces are outlined. The dosage, mode of administration of the drug, and toxic reaction are reviewed.

In the authors' experience, streptomycin has been a most valuable adjunct in the surgical treatment of pulmonary tuberculosis, and has proved efficacious for the following indications:

- 1 Preoperatively and postoperatively for all pulmonary resections and intrapleural surgery on tuberculosis patients
- 2 Preoperatively and postoperatively for all thoracoplastics considered substandard risks, or with complications such as contralateral pneumothorax, diabetes, etc
- 3 For acute exudative postoperative spread, in cases in which streptomycin has not been used prophylactically
- 4 Intrapleurally, for pure tuberculous empyema without bronchopleural fistula
- 5 In combination with open Schede thoracoplasty for tuberculous mixed empyema with bronchopleural fistula
- 6 In infected chest wounds and sinuses

JOHN J. MALONEY, M D

The Role of Streptomycin in the Surgery of Pulmonary Tuberculosis PAUL T. CHAPMAN, E. J. O'BRIEN, PAUL V. O'ROURKE, and BRUCE DOUGLAS *J Thorac Surg*, 1949, 18 15

Patients receiving streptomycin were divided into the following groups:

Group 1 Those in whom the authors hoped that collapse or other surgical measures could be avoided or reduced in amount.

Group 2 Those in whom surgical procedures (contraindicated because of the patient's condition) could be made possible through streptomycin.

Group 3 Patients who received the drug as a prophylactic measure against spreads following surgical and collapse procedures or as a means of clearing these spreads if they occurred, and of making operation possible at an earlier time.

Group 4 Patients with proved or suspected tracheobronchial disease.

In Group 1, composed chiefly of patients with early, minimal, and moderately advanced disease, the authors have found that streptomycin has decreased the necessity of collapse measures by over 50 per cent. Even in more extensive disease, the results are sometimes so startling that further procedures are found unnecessary to complete the arrest of the disease.

In Group 2, the authors have found that the number of patients in whom surgical procedures (especially thoracoplasty) were possible was doubled by the administration of streptomycin. Many lesions seen before the administration of streptomycin were so extensive and of such character that collapse measures could not be performed. Also, the condition of many patients was too grave, and there were complications such as gastrointestinal, peritoneal, pelvic tuberculosis contraindicating surgical procedures. Streptomycin is markedly effectual in these complications, and after they have subsided and sufficient clearing of the lesion has taken place surgical procedures may frequently be completed with the expectancy of good results. The authors have often seen patients who were extremely ill, with high temperature and dyspnea (some almost moribund and in oxygen tents), in whom the temperature became normal rapidly, the oxygen tent was removed, and the patients continued to improve, making surgical procedures (with good results) possible later.

Group 3 somewhat overlaps Group 2, but is considered separately. This group includes patients in whom major procedures are contemplated, in whom soft lesions exist on the operation side, or an unstable lesion is present in the contralateral lung. Streptomycin is used here to prevent contralateral spread, and to clear or protect the contralateral lesions during and after surgery. In Negroes and others with known lack of resistance, the use of the drug is imperative. The authors are now operating on much softer lesions, earlier, and have observed fewer spreads since they have used streptomycin. They now believe that in all patients undergoing major surgical procedures it should be used prophylactically.

With regard to Group 4, there is no question as to the results obtained in proved ulceration. These lesions often heal as if by magic soon after the drug is started. The number of bronchoscopies performed for these lesions has been strikingly reduced. Prolonged treatment with silver nitrate is no longer necessary. Bronchoscopy is now done for diagnosis, and again after streptomycin therapy, the latter being virtually unnecessary, however, except for statistical purposes, because it is so rare not to find ulcers healed after streptomycin therapy.

As would be expected, the results were most striking in soft, mixed, and in the majority of recent lesions. However, occasionally in apparently old, fibrotic lesions excellent results have been obtained.

In almost all patients, some clearing of the lesions and clinical improvement have been noted. One of the great problems is to know what to do with these "old chronics" in whom the outlook seems hopeless. If we give streptomycin to them as a last resort, we shall probably tend to put the drug into disrepute.

In the authors' experience, the results of streptomycin therapy, in properly selected patients, have frequently been so amazing that there is an inclination to be overzealous in our attitude toward it.

JOHN J. MALONEY, M.D.

An Evaluation of Streptomycin as a Protective Agent in Pulmonary Resection for Tuberculosis
JULIAN A. MOORE, JAMES D. MURPHY, and PARKER D. ELROD. *J. Thorac. Surg.*, 1949, 18: 45

The authors are of the opinion that streptomycin is a suppressive or bacteriostatic agent of proved value against the tubercle bacillus. It is not a cure for tuberculosis. In certain types of cases, however, it has proved to be of inestimable value in controlling the disease. They believe that it is too early for any one to attempt to assess its value in the treatment of tuberculosis, and that this cannot be done until several years have elapsed. From their clinical experience they consider that its chief place in the treatment of tuberculosis is as an adjunct to establish collapse procedures. With the use of streptomycin it has been possible for them to perform a lobectomy or a pneumonectomy for tuberculosis with a low morbidity and mortality rate and with excellent early results.

If the late results following pulmonary resection prove to be as gratifying as those after thoracoplasty, it is believed that indications for resection will be greatly extended.

JOHN J. MALONEY, M.D.

Comparison of Results in 200 Consecutive Resections for Pulmonary Tuberculosis
CHARLES P. BAILEY, ROBERT P. GLOVER, and THOMAS J. E. O'NEILL. *J. Thorac. Surg.*, 1949, 18: 36

From the authors' appraisal of their entire experience with pulmonary resection for tuberculosis, they have come to the conclusion that the beliefs first voiced upon the use of streptomycin in resection for pulmonary tuberculosis, by Glover, Clagett, and Hinshaw, are essentially corroborated. Provided that a previous course of streptomycin therapy has not rendered the patient bacteria streptomycin-fast, a definite suppression of the tuberculous process is produced during preoperative therapy. The patient's disease then temporarily assumes a more chronic course, so that it can be subjected to surgery with a much greater margin of safety. In the treated group, the incidence of tuberculous operative spreads and flare-ups become practically nil. Infections of the pleura and chest wall were remarkably reduced in spite of the inclusion of 14 cases of empyema (with proved bronchopleural fistula in 12 cases) in the streptomycin-treated group.

The complications which are essentially due to the resection rather than to the tuberculosis were un-

changed. While more difficult cases were frequently chosen for surgery in the streptomycin-treated group, improvements in surgical technique reduced the nonspecific complications and mortality about the same.

The authors believe today that the mortality in pulmonary resection for tuberculosis can be set at any figure over 5 per cent (dependent upon the type of case selected for resection) and the choice between radical or conservative management must be left to the judgment of each individual clinic.

JOHN J. MALONEY, M.D.

Disposal of the Bronchial Stump in Lobectomy and Pneumonectomy for Bronchiectasis
ERIK UNONIUS. *Acta chir. scand.*, 1949, 97: 442

As long as the tourniquet method was used, with or without separate ligation or suture of the vessels and bronchus, infection of the mediastinum and pleura, bronchial fistula, abscess around the stump, late hemorrhage, and sepsis were frequent sequelae. The technique of dissecting the hilus and disposing of the vessels and bronchi separately, however, did not itself ensure satisfactory results. The method of closing the bronchi is of great importance. The structures in the hilus of the part of the lung to be resected are anatomically dissected. After ligation of the vessels, the bronchus is divided and the outermost ring of cartilage is removed for the purpose of obtaining a soft invaginable stump. The edges are coated with 3 or 4 interrupted silk sutures, avoiding the mucous membrane. The stump is closed with a continuous catgut suture. The corners are invaginated with silk, and the midpart of the bronchus with a few interrupted silk sutures. The wound in the mediastinum is powdered with a mixture of 30,000 units of penicillin and 5 gm. of sulfathiazole, and the stumps of bronchi and vessels are then buried separately into mediastinal tissue. A continuous pleural suture then closes the entire area.

Forty-nine of 53 patients so treated recovered. No case of insufficiency of the bronchial stump occurred, the stump in each case healing by first intention.

SAMUEL KAHN, M.D.

On Abscess of the Lung
V.-M. ANTONEN and HEINO LAITINEN. *Ann. med. int. fenn.*, 1948, 37: 183

The present article is based on a study of 106 patients with lung abscess who were treated at Kivela Hospital, Helsinki, and in the Third Medical Department of the University of Helsinki. More than one-half of the patients were between 30 and 50 years of age, and 75 per cent of them were males. The primary diseases were pneumonia, primary atypical pneumonia, bronchiectasis, sepsis, and pulmonary tumor. In 94 per cent of cases the abscesses were single. It is pointed out that multiple abscesses may result from conditions such as bronchiectasis, as well as from bacterial embolism. In this series the symptoms were fever, cough, pain, purulent sputum, bloody sputum, loss of weight, and weakness. The causative agents were mostly penicillin-sensitive.

aerobic cocci. It is suggested that a cavity with a fluid level represents a phase in lung abscess. It is sometimes intermittent, and frequent x-ray studies are necessary in some cases. Abscesses occurred more often in the right lung than in the left.

From a therapeutic standpoint, it is believed that medical care with combined sulfonamide-penicillin therapy is efficacious in a high percentage of cases of lung abscess. Treatment with these drugs can be followed safely for a longer period than the usually accepted 2 months.

The complications in this series were pleural empyema, exudative pleurisy, amyloidosis, and profuse lung hemorrhage.

ROBERT E. FLORER, M.D.

Clinical Considerations in a Case of Tumor of the Upper Lobe of the Right Lung (Pancoast's Syndrome) with Secondary Infection, Diffusion of the Process to the Right Supraclavicular and Laterocervical Region, and Subsequent Fistulization (Considerazioni cliniche su di un caso di tumore del lobo superiore del polmone destro [sindrome di Pancoast] con infezione secondaria, diffusione del processo alla regione sopraclavicolare e laterocervicale destra e successiva fistolizzazione) VINCENZO MIADONNA *Minerva med.*, Tor., 1949, 40: 69

This case of lung tumor was observed in a man of 40 years, in whom an adenocarcinoma originated in a bronchus and developed superficially in the right pulmonary apex, and thereby caused Pancoast's syndrome. The onset of the tumor was evidenced by a bronchopneumonic process in the pulmonary zone depending from the bronchus which was involved by the tumor. The process spread to the supraclavicular and laterocervical lymph nodes and soon invaded these two regions entirely. Simultaneously, infection of the tumor occurred, probably through some bronchus in which the secretions stagnated and offered a favorable medium for the development of the bacteria. The infection spread to the entire neoplastic mass, causing a phlegmon of the jugular region and the appearance of fistulas in the right supraclavicular area. The course of the disease was marked by intense pain which required the use of large doses of narcotics. Death occurred 16 months after the onset of the first symptoms.

It is recognized that pulmonary tumors can at times appear suddenly, as if they were common bronchopneumonic foci, but the present case was peculiar. In June, 1945 an opacity of bronchopneumonic type in the stage of resolution was observed in the subclavicular region, while in December the clinical and roentgen pictures differed in site and aspect: there was no trace of the previous opacity, but another more marked and completely different shadow had appeared in the apical zone. It is difficult to establish a pathogenetic connection between these two findings and the literature is silent on the subject, but a study of the case allows the following deductions:

The diagnosis of a bronchopneumonic focus was correct, the focus presented an irregular course and

delayed resolution but eventually healed as examination 2 months later demonstrated the disappearance of the shadow and clinical signs. However, the patient continued to have his disturbances and his general condition did not improve, then another examination revealed the apical opacity with its peculiar aspect.

The bronchial secretion is carried upward by the action of cilia of the bronchial epithelium, but at some point this epithelium is altered by the presence of a tumor, some stagnation of the secretion must result below the alteration even if the bronchial lumen is not decreased. This explains how the seat of the inflammatory focus may be totally different from that of the tumor, and also how the inflammatory focus may undergo resolution through the normal processes of immunization.

As the tumor developed superficially in the apical zone, it would seem difficult to establish its point of origin in a bronchus. But it must be remembered that a tumor sometimes does develop far from its bronchial origin and that the histologic aspect of the present tumor, an adenocarcinoma, demonstrates its origin from the elements of the bronchial glands.

RICHARD KEMEL, M.D.

Diagnosis of Carcinoma of Lung LEWIS B. WOOLNER and JOHN R. McDONALD *J. Am. M. Ass.*, 1949, 139: 497

An analysis of 200 cases in which a diagnosis of carcinoma was made on the basis of examination of smears of sputum or bronchial secretions was carried out. In 190 cases a final diagnosis of bronchogenic carcinoma or pulmonary metastatic carcinoma was made. In 4 cases a carcinoma in the esophagus, larynx, or trachea was demonstrated. In 4 cases the diagnosis was proved to be falsely positive. In the remaining 2 cases the final diagnosis was uncertain.

Exfoliated carcinoma cells in sputum or bronchial secretions provided the only preoperative microscopic evidence of cancer in 29 of 74 cases of bronchogenic carcinoma in which surgical exploration was carried out. In 13 cases of bronchogenic carcinoma in which the lesion proved removable, a preoperative diagnosis of cancer was based on the cytologic characteristics of the sputum or bronchial secretions. In 6 cases of Pancoast's tumor and in 4 cases of alveolar cell tumor there were carcinoma cells in the sputum.

Cytologic examination of sputum is of great diagnostic value in the case of patients suspected of having bronchogenic carcinoma and in whom bronchoscopic examination is contraindicated.

Carcinoma of the Lung with Intracranial Metastasis: Successful Removal of Metastatic and Primary Lesions H. THOMAS BALLANTINE, JR., and FRANCIS C. BYRON *Arch. Surg.*, 1949, 57: 819

The authors have estimated that the incidence of intracranial metastasis from pulmonary carcinoma (based on data from several sources) is 23 per cent. The accepted theory with regard to the occurrence of metastases is based on the fact that the carcinoma

cells can enter the blood stream without passing through the capillary filter of the lung. The authors cite several reports of cases in which the patients lived from 2 months to 6½ years after removal of metastatic lesions. A case is presented in which both the metastatic lesion and the primary lesion were removed. The authors state that they were unable to find in the literature any report of such a case.

The patient was a 54 year old white man who complained of left-sided weakness, jacksonian epileptic attacks, and uncontrolled movements of the left foot. At operation, a subcortical cyst in the region of area 4 was removed, and radical extirpation of carcinomatous tissue in this area was done. Later a pneumonectomy was performed. Five months after the last operation there was residual spastic paresis of the left leg. There was no evidence of recurrence of either carcinoma.

The authors state that in dealing with these cases, frequently one must consider the brain lesion first because of the patient's intolerance to increased pressure from these expanding lesions. Care must be taken to localize the intracranial lesion as much as possible before surgery. Craniotomy is indicated in the presence of only two well localized intracranial lesions, whether or not the primary tumor can be removed.

ROBERT E. FLORER, M.D.

Pulmonary Resection for Metastatic Malignancy DOUGLAS ROBB *Brit J Surg*, 1948, 36 200

Prompted by Alexander and Haight's report in *SURGERY, GYNECOLOGY AND OBSTETRICS* (1947, 85 129), of 24 collected cases (19 of their own and 5 collected) of resected pulmonary metastases in which 12 patients survived without recurrence for periods varying from 1 to 12 years, the author reports 3 cases of resection of metastatic hypernephroma to the lung.

In the first case a 42 year old woman had a left nephrectomy for hypernephroma of 4 years' duration. Eight years later a tumor developed in the left lower lobe for which left lobectomy was performed 6 years later. This patient has remained disease-free for 2½ years.

In the second case a 63 year old man had a right nephrectomy for hypernephroma, which was followed 6 years later by cough and blood-stained sputum. Left pneumonectomy disclosed metastatic hypernephroma in the lower lobe, with two small nodules in the anterior border of the upper lobe. After metastases became apparent in other sites, 11 months after pneumonectomy and at 14¼ months, the patient died with widespread multiple metastases involving the original site, the inferior vena cava, the diaphragm, and the right lung.

In the third case a 65 year old woman was not followed up after pneumonectomy. She was found to have an abdominal tumor 10 years before right nephrectomy was done, 10 years later symptoms of lung tumor developed. Left pneumonectomy disclosed metastatic hypernephroma at the hilum, with a small nodule near the edge of the lower lobe.

It is characteristic of hypernephroma metastases to appear after long intervals of apparent surgical cure of the primary lesion. Also, occasional cases of spontaneous regression of pulmonary metastases are reported (*Surg Gyn Obst*, 1937, 65 433).

Chest films at 3 to 6 month intervals up to 10 years after nephrectomy are recommended as an important feature of the follow-up of hypernephromas.

FRANK B. QUEEN, M.D.

Experimental and Clinical Studies of the Role of Streptomycin in the Pleural Cavity EDWARD J. BEATTIE, JR., BRIAN BLADES, and CHARLES HORTON *J Thorac Surg*, 1949, 18 25

Experiments and clinical studies were carried out to determine the pathologic effect and the absorption rate of streptomycin in the pleural cavity.

Operations were performed on 9 dogs. Three of these received 100 c.c. of saline into the pleural cavity, and biopsies were taken from the pleura 7 days later. Six of the dogs received 0.5 gm of streptomycin in 100 c.c. of saline into the pleural cavities. Streptomycin assay studies were carried out on pleural fluid and venous blood. Biopsies of the pleura were performed 7 days after injection.

The absorption rate of streptomycin in the pleuras of dogs was rapid and the maximum blood levels were reached in 30 to 60 minutes.

There were no apparent differences in the microscopic picture of the pleura of animals receiving saline and of animals receiving streptomycin.

Twelve humans received streptomycin intrapleurally. These 12 cases can be subdivided into 6 cases of unscarred pleura, 2 cases of moderately scarred pleura, and 4 cases of markedly scarred pleura. The absorption curves were similar in all three types. The absorption is rapid, maximum absorption usually occurs in 30 minutes and falls to low levels in from 6 to 8 hours.

The following conclusions are drawn:

No harmful effects were seen either in the gross or the microscopic picture of pleura removed from dogs 7 days after the dogs received streptomycin in the pleural cavity.

The absorption of streptomycin from the pleura of dogs and human beings is rapid and high levels are reached.

Scarred pleuras were found to absorb streptomycin as well as unscarred pleuras.

JOHN J. MALONEY, M.D.

Streptomycin in Surgical Patients EDWARD J. BEATTIE, JR., and BRIAN BLADES *J Am M Ass*, 1949, 139 902

The value of streptomycin as an adjunct to the surgical treatment of pulmonary tuberculosis is shown. Since 1933 approximately 600 cases of resection for pulmonary tuberculosis have been reported, in these there was a 25 per cent mortality rate with 12 per cent empyemas and 8 per cent bronchopleural fistulas. Since the preoperative and postoperative use of streptomycin, there has been a re-

duction in the number of complications due to tubercular spread as well as a reduction in the immediate operative mortality. Not enough time has elapsed to determine whether the long range survival rate will be better in patients treated with streptomycin than in those undergoing resection for pulmonary tuberculosis prior to the use of streptomycin.

One gram of streptomycin in two divided doses appears to be the optimum amount. Streptomycin therapy should be started 7 days prior to, and continued for 14 days after, operation. This dosage almost completely obviates toxic effects. The pleural absorption of streptomycin is rapid and high levels are reached in 1 hour. Resistance of the tubercle bacillus to streptomycin develops soon, some evidence indicating that this can occur within 40 days.

With the added protection which streptomycin affords pulmonary resection for tuberculosis, it is technically possible to carry out major resection in desperate risk patients. In view of the fact that resistance of the tubercle bacillus to streptomycin develops, it is important that streptomycin be reserved for surgical treatment in any case which may be potentially surgical, and not be used in instances of minimal pulmonary tuberculosis.

C. FREDERICK KITTLE, M.D.

HEART AND PERICARDIUM

An Experimental Study of Collateral Coronary Circulation Produced by Cardiopneumonopexy

B. NOLAND CARTER, EDWARD A. GALL, and CHARLES L. WADSWORTH. *Surgery*, 1949, 25: 489.

In view of the prevalence of coronary artery disease, several intensive studies have been directed within the last decade toward devising means of producing collateral coronary circulation. Several possible sources of such a collateral blood supply exist: the thoracic wall, including the pectoral muscles, the internal mammary artery, and the intercostal arteries, the pericardium, the omentum, and the lung. Investigators in this country and abroad have undertaken experimental studies utilizing various of these sources.

The results of the experiments described clearly indicate that vascular communications between the heart and the adherent lung can be produced by cardiopneumonopexy. They also show that the survival rate following ligation of the anterior descending branch of the left coronary artery is significantly improved following this operation and that the degree of myocardial damage is decreased. There are, however, several important physiologic questions which should be answered and which are concerned with the practical applicability of the procedure. These are chiefly three in number: (1) What is the direction of the blood flow and is it from the lung to the heart or vice versa? (2) How great a volume of blood can be delivered through the newly established channels and how long will such channels continue to function? (3) What is the degree of oxy-

genation of the blood supplied through the collateral vessels arising from the pulmonary circulation?

Gross and microscopic evidence has been obtained that by this operation new vascular channels can be produced between the myocardium and the adherent lung, but the amount of blood flow, the direction of the flow, and the duration of the patency of these channels has not been established.

In the instances in which cardiopneumonopexy was performed on normal hearts, injections of 10 per cent suspension of India ink in blood at normal pressures revealed some filling of the superficial vessels in the myocardium, but in the case of hearts rendered ischemic by coronary artery ligation there was considerably greater filling not only of the superficial vessels but of the deep ones as well.

Comparison of specimens obtained from dogs in which ligation of the anterior descending branch of the left coronary artery had been performed after cardiopneumonopexy with specimens from dogs in which ligation alone was done revealed less extensive infarcts and a lower mortality in the protected series. Therefore, the mortality in the protected series was 20 per cent, and in the animals with simple ligation it was 48 per cent. Severe infarction occurred in 75 per cent of the animals with simple ligation, but in only 23 per cent of the animals with ligation subsequent to cardiopneumonopexy.

JOHN E. KIRKPATRICK, M.D.

Experimental Anastomoses of Vessels to the Heart

FRANK GERBODE, JAMES YEE, and F. F. RUNDLE. *Surgery*, 1949, 25: 556.

Superior vena caval obstruction is frequently due to aneurysm or tumor, but in cases in which it is due to one of the various types of fibrosing mediastinitis it has been considered possible that the establishment of an alternative venous route to the heart will relieve the attendant symptoms of elevated venous pressure of the upper extremities and trunk, edema, and pleural effusion.

Using dogs, the authors have devised three operations for the relief of superior vena caval obstruction.

1. Approximately one week after placing a constricting ligature about the superior vena cava, above the level of the azygos vein, the azygos vein was anastomosed to the superior vena cava with the result that there was relief from the symptoms of vena caval obstruction. In a similar fashion, obstruction was produced at a level below the junction of the azygos, and relief was obtained by anastomosis of the azygos vein to the right auricle. It was hoped that the azygos would dilate somewhat to accommodate the physiologic load, however, this did not occur, and in several animals elevated pressures and angiograms indicated occlusion at the sites of anastomosis. Autopsy of these animals showed fibrosis and narrowing supposedly due to the muscularity of the auricular wall.

2. An atriocaval anastomosis was developed to create a shunt around the experimentally produced obstruction made below the level of the azygos. The

SURGERY OF THE THORAX

technique is sketched in the original article. There were no deaths following this procedure. Seven of the 10 animals having this shunt had a normal postoperative course, without exhibiting the usual signs of occlusion of the superior vena cava. Three animals developed late thromboses at the suture line, and in each instance some technical explanation could be furnished. Three of the animals have been followed up for more than a year and are known to have no arrhythmia detectable in the postoperative electrocardiograms. It is suggested that inasmuch as these anastomoses between the superior vena cava and the auricle are technically possible, such anastomoses might be applied to man under suitable circumstances.

JANE C. MACMILLAN, M.D.

ESOPHAGUS AND MEDIASTINUM

Retained Food Remnants in Esophageal Diverticula Resembling Tumor and Dysphagia in Cases of Small Esophageal Diverticula at the Bifurcation Level SVEN ROLAND KJELLBERG
Acta radiol, Stockh., 1948, 30 435

The author stresses the similar roentgenological appearance produced by a polypoid neoplasm of the esophagus and a diverticulum of the esophagus when the latter is partially filled with food. He cites 2 illustrative case histories in females aged 45 and 66 years, respectively. They presented a history of intermittent dysphagia which was most pronounced during the ingestion of solid food. Barium swallow in both patients revealed a filling defect in the esophagus at the level of the tracheal bifurcation suggesting a polypoid tumor. Repeat examination 2 weeks later, however, visualized a large diverticulum at the same site. This presumably contained food remnants during the first study. The diagnosis of esophageal diverticulum was suspected because of

Fig 1 (Kjellberg) On a level with the bifurcation a contrast defect can be seen in the esophagus resembling a tumor

the character of the dysphagia, it was intermittent, of long duration, and worse with solid food or large particles.

Tuberculous Esophageoepigastric Fistula (Fistola esofago-epigastrica tuberculare) VALENTINO DE FAZIO
Riforma med, 1949, 63 145

An extremely rare esophageocutaneous fistula of tuberculous origin and with its external orifice in the epigastric region, is reported by the author.

The patient was a man aged 26 years. Five years prior to admission to the hospital he developed pain in the right hip which subsided after 7 months. Roentgenograms of the spine were negative. Two

Fig 2 (Kjellberg) A check examination one week later shows the diverticulum filled with contrast substance

years later the patient noticed a hard, small tumefaction in the gluteal region from which a fistula developed. The diagnosis of sacroiliac arthritis was made. After a few months the condition subsided. Several months later severe pain developed in the right hypochondriac region and was followed by the appearance of a tumefaction, which in turn led to the formation of a fistula.

After the injection of lipiodol, an elongated sac leading toward the right costal arch and from there to the stomach was visualized.

Further x-ray studies established the existence of a connection between the fistula and the thoracic portion of the esophagus.

Six similar cases have been reported in the literature. The absence of subjective symptoms focusing attention on the esophagus, such as dysphagia, was noticed in all cases.

The author believes that tuberculous lymphadenitis was responsible for the condition, but a focus in the bones could not be excluded.

Drainage of the sac, followed by x-ray therapy, produced a cure.

JOSEPH K. NARAT, M.D.

The Treatment of Mediastinitis from Perforation of the Esophagus ARNE HOMB *Acta chir scand*, 1948, 97: 189

The esophagus in almost the whole of its course stands in close relation to various vital organs, and a perforation thereof may easily lead to serious complications. The most frequently encountered of these is infection of the mediastinum. It is especially the posterior part of the mediastinum that is of interest in case of perforation of the esophagus. It is bounded posteriorly by the spinal column and the prevertebral fascia and in front by the layer of fascia on the anterior side of the trachea. At the level of the bifurcation this latter fascia is connected with the bronchi, and here the downward diffusion of infections is to some degree prevented, a fact which is important with regard to treatment.

According to their cause, the esophageal perforations are divided into two main groups, one of which comprises the cases due to malignant tumors and the other, cases due to foreign bodies and injuries.

Cancer of the esophagus often leads to spontaneous perforation, but this usually develops gradually and does not so often give rise to extensive infection of the mediastinum. As it generally denotes a terminal stage of the disease, it is of minor interest from a therapeutic standpoint.

Perforations caused by foreign bodies are of greater practical importance. Most often, sharp bodies are present, but blunt objects may also perforate when they have been lying in the gullet for some time and decubital ulcers develop.

Three cases of mediastinitis due to perforation of the esophagus are described. All 3 patients had retained foreign bodies. Two of them had drunk lye when they were children and had since had symptoms of stricture. In one case the perforation occurred during an attempt to introduce a stomach

tube, in the 2 other cases it occurred during exploration with an esophagoscope.

In the first case there developed a large, but circumscribed, mediastinal abscess. This was at first drained by means of cervical mediastinotomy, but as it later descended to the level of the ninth thoracic vertebra and the drainage became unsatisfactory, a posterior mediastinotomy had to be performed afterward. The patient had also empyema on the right side, which yielded to puncture treatment and injections of penicillin.

The second patient had a large perforation and developed diffuse mediastinitis, which was drained by a posterior mediastinotomy with a good result.

The third patient had a small lesion on the wall of the esophagus and a circumscribed mediastinal abscess developed, this was drained from the left side of the neck. However, drainage was not satisfactory. The abscess descended and the evacuation proceeded slowly. Perforation to a bronchus occurred on the right side with symptoms of a fistula between the esophagus, the abscess cavity, and the bronchial tree. The fistula closed later.

Penicillin-sulfonamide treatment did not prevent the development of a mediastinal abscess in the first case or check the progress of a phlegmon in the second, however, in these cases there were large perforations causing extensive infections. In cases of such large perforations infective matter will be constantly conveyed to the mediastinum from the esophagus, and it is not reasonable to expect that the penicillin and sulfonamides alone will be able to master the infection. Surgical intervention with drainage will, therefore, be necessary.

The author's experiences have also confirmed the view already mentioned, that infections in the mediastinum which are descending deeper than the level of the fourth thoracic vertebra cannot be satisfactorily drained through an incision in the neck, but must be treated by posterior mediastinotomy.

After giving a brief survey of the clinical features, prognosis, and treatment of mediastinitis occurring after perforation of the esophagus, the author reports 3 cases of his own, which were treated by sulfonamides, penicillin, and mediastinotomy with good results. While the prognosis in mediastinitis was formerly very unfavorable, the case histories published in recent years seem to show that an essential improvement in this respect has taken place since the use of sulfonamides and penicillin has been adopted in the treatment. Meanwhile, it is not likely that these remedies will render surgical intervention superfluous.

MISCELLANEOUS

Comparison of Thymic Hyperplasia in Myasthenia Gravis and Exophthalmic Goiter ALLEN L. BRYAN, JOHN R. McDONALD, and O. THERON CLAGETT *Arch Path*, Chic, 1948, 46: 212

The present article concerns 23 proved cases of myasthenia gravis, exclusive of thymoma, in which

thymectomy was done. In 4 patients extreme lymphoid hyperplasia, and in 2 patients, moderate lymphoid hyperplasia of the thymus were observed on microscopic examination. In the remainder, the glands either were normal or had been replaced by fat.

Twelve of the 17 normal glands in the myasthenia series showed areas of hyperplasia, but the percentage of glandular tissue was too low to permit their being considered hyperplastic, the average content of thymic parenchyma being only 29 per cent.

In none of the 20 cases of hyperthyroidism due to exophthalmic goiter did extreme hyperplasia of the thymus occur, and in only 1 case did moderate lymphoid hyperplasia occur.

Small areas of epithelial clustering occurred in 2 cases of the myasthenia series and in 3 cases of the hyperthyroid series, but the glands were essentially normal.

When the actual amount of glandular tissue in the thymus was determined and compared with Hammar's weights and with planimetrically determined percentages of thymic tissue in these glands, the weight of the parenchyma of 2 of 13 glands in the myasthenia series significantly exceeded the upper limit of normal, while the weight of the parenchyma of 7 of 9 glands in the hyperthyroid series exceeded the upper limit of normal.

There was apparently no correlation between the extent of hyperplasia determined microscopically and that which was observed when the actual weight of essential thymic elements exceeded significantly the expected upper limit of normal.

There was no correlation, on the basis of microscopic observations, between the extent of hyperplasia of one lymphoid organ and that of another in this study.

No correlation was found between the clinical and microscopic findings in myasthenia gravis, excluding the thymomas.

The term "thymoma" might be defined as a circumscribed tumor of the thymus composed of architecturally disarranged thymic elements, often with dense dividing trabeculae, and usually devoid of adult fat cells.

Thymoma HUGH REID and R. MARCUS *Brit J Surg*, 1949, 36 271

The subject of thymic tumors in general is reviewed from a historical standpoint by the authors, including the pathologic classification and the relation to myasthenia gravis. Some of this information is summarized in tabular form.

The authors observed 5 patients who were considered to have tumors of thymic origin. Three of these had myasthenia gravis. In 2 the tumor was removed surgically by a sternum-splitting approach. One of these died. In 1 case the chest was explored by means of a transpleural approach but the tumor could not be removed. In another instance the tumor, apparently invading the anterior chest wall, was subjected to biopsy examination only. Two patients were treated by roentgen therapy, as was the inoperable tumor.

The tumors were classified as reticulum cell carcinomas in 3 instances. In one case there was no histologic diagnosis and in the other the tumor consisted of large masses of lymphoid tissue without Hassall's corpuscles or lymphoid follicles. Reticulum cells were prominent and often packed into groups.

The article is illustrated by photomicrographs and roentgenograms. HIRAM T. LANGSTON, M.D.

A Case of Thymolipoma G. F. M. HALL. *Brit J Surg*, 1949, 36 321

This report concerns the occurrence of a benign asymptomatic mediastinal tumor composed of fat and thymic tissue, and believed to be comparable to one other found in the literature.

The tumor was found at autopsy in a 47 year old man in good health, who died promptly after severe trauma. It measured 22 by 16 by 6 cm and weighed 1100 gm; it was pear-shaped in outline and was found arising from the anterior mediastinum but lying almost entirely within the right pleural cavity. On cut section the mass appeared to consist of a fatty matrix with small scattered areas of firmer consistency. Histologic sections showed the main bulk of the tumor to consist of normal-appearing adipose tissue. The other areas had the appearance of thymic tissue, most of which was compatible with normal thymic structure. One such area, however, was different from the rest in that it was better encapsulated and suggested an adenoma of the thymic reticulum cells.

The tumor was believed to justify the name of thymolipoma because it was argued that both the adipose and the thymic portions were concerned in the production of the tumor.

The possibility that many intrathoracic "lipomas" may have an origin similar to that of this tumor and that under such circumstances the thymic elements may merely be overlooked is discussed. The article contains gross and microscopic illustrations.

HIRAM T. LANGSTON, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Some Observations on the Functional Anatomy of Inguinal Hernia and Its Bearing on the Operative Treatment DAVID H. PATEY *Brit J Surg*, 1949, 36 264

After operative exposure of both indirect and direct inguinal hernias, the author studied the functional anatomy of the surrounding structures by stimulating the conjoint internal oblique and transversalis muscles by faradic current. The following findings resulted:

1 Indirect inguinal hernia

a The pillars of the transversalis fascial sling constituting the medial margin of the internal ring are pulled laterally and upward as described by Lytle.

b The arched fibers of the internal oblique constituting the lateral margin of the internal ring move medially.

These two structures thus form a shutter closing the ring by operating in different planes. This protection is further supported in a minor way by (1) contraction of the cremaster fibers branching up the cord and tending to plug the ring, and by (2) the pull of the attachment of the internal oblique to the inguinal ligament, elevating the latter and so protecting the ring from below.

2 Direct inguinal hernia

a The transversalis fascia becomes tightened through the pull on its attachment to the deep surface of the transversalis muscle.

b By the contraction of the combined internal oblique and transversalis muscles immediately above the transversalis fascia, the upper limits of the direct inguinal hernia area are supported. The direction of movement is lateral, which tightens the medial tendinous part. This gives the effect of a hook rather than an arch. On contraction, there is a general movement of the whole structure laterally toward the muscular part, as well as the embracing and protective action of the internal ring of the muscular hook itself.

c The inguinal ligament becomes tightened by the pull of the internal oblique attachment to it and also by the contraction of the external oblique, so that the lower edge of the direct inguinal hernia area is supported.

The main support is therefore the transversalis fascia.

These findings suggested the following procedures:

1 Indirect inguinal hernia

The shutterlike action of the internal ring is reinforced by cutting a strip of fascia from the posterior lamella of the anterior rectus sheath and leaving its lateral edge attached. The strip is then brought through the internal oblique muscle immediately anterior to the medial edge of the ring. The strip is then passed through the upturned edge of the

inguinal ligament and sutured, thus embracing the medial margin of the ring closely. This tightens with each contraction of the attached muscles and further helps to close the ring.

2 Direct inguinal hernia

A continuous suture of fascia lata (Gallie) is used, being placed from below upward and laterally in an oblique direction, so that its loops get well tightened at each contraction and give maximal support to the underlying transversalis fascia. This is important since the shutterlike mechanism of the conjoint tendon, as postulated by Keith, does not exist, and the main protective agent for the direct inguinal area is a tightened transversalis fascia.

LEROY J. KLEINSASSER, M.D.

Benign Paroxysmal Peritonitis. Second Series SHEPPARD SIEGAL. *Gastroenterology*, 1949, 12 234

The author reported his first series of cases of benign paroxysmal peritonitis in 1945, and an additional 6 cases are recorded in the present article. The disease is often confused with acute abdominal conditions requiring surgery; it is a disease of young people, is chronically disabling, and may last a lifetime. It may begin in childhood or, most often, in the second or third decade of life, and both sexes are affected. Recurrent paroxysms of abdominal pain and fever constitute the chief complaint. The attacks are usually of 2 or 3 days' duration, the hyperacute, febrile period lasting from 24 to 36 hours. The maximum temperature elevation varies from 100 to 105 degrees. Abdominal tenderness is invariable, and involuntary spasm of the abdominal wall is occasionally present. Constipation, vomiting, and leucocytosis are the rule. The pain is frequently localized in the right lower quadrant, thus simulating acute appendicitis. Chest pain of a pleuritic type is an occasional symptom. In most of the cases recorded in the literature the patients have been either Jewish or Armenian.

The etiology of the disease remains obscure, however, it apparently is closely related to the allergic disorders. Its onset in early life, its paroxysmal recurrence over many years without impairment of health, its basis in a reversible vascular reaction of hyperemia and edema are all consistent with this concept. Of 11 patients, 2 were atopic and 4 more had a definite family history of allergy; however, causative food allergens have not been demonstrated in any of 5 cases completely studied from this point of view. Eosinophilia has not been present in the author's patients during acute attacks, nor has adrenalin or the antihistamine drugs produced relief.

Three patients have been operated upon during an acute crisis. Hyperemia or edema of the peritoneum, with or without serous or serofibrinous exudate, comprise the operative findings. Interval explorations have been negative.

Treatment of the disease should include careful search for specific allergens and psychiatric evaluation. Surgical exploration is sometimes indicated if an intra-abdominal surgical lesion cannot be excluded. However, in 4 of 6 cases included in this report, appendectomy was done with no beneficial effect on the course of the patient's disease.

FREDERICK W. PRESTON, M.D.

GASTROINTESTINAL TRACT

Hematemesis D. C. LEWIN and SIDNEY TRUELOVE
Brit. M. J., 1949, 1, 383

The present report covers 305 cases of hematemesis admitted to the Radcliffe Infirmary during the period from 1938 to 1947. The mortality was 19 per cent (58 deaths). A history of proved or probable chronic peptic ulcer was reported in 208 of the patients.

Age was the most important factor influencing prognosis, for the whole series as well as for the group with chronic peptic ulcer. The mortality rate rose steeply during the age period from 40 to 50 years.

In patients with chronic peptic ulcer, a long or short history of ulcer had little bearing on the immediate prognosis. This was true even in the older age group in whom one would normally expect to find a greater number of chronic ulcers.

The frequency of recurrent bleeding was about the same in old and young patients, and about the same proportion received massive blood transfusions.

The authors believe that general bodily changes occurring with advancing age are the principal causes for the higher mortality rate. The same is true of the other frequent complication of peptic ulcer—perforation.

Very few patients in this series were treated surgically, therefore, the authors have said nothing (as has been mentioned frequently in other articles) about the value of early decision and early surgery as a measure that tends to lower mortality in hematemesis in patients over 40 years of age.

FREDERICK C. HOEBEL, M.D.

Argentaffine Tumors of the Gastrointestinal Tract
Report of 11 Cases CHARLES H. BROWN, ROGER P. BISSENETTE, and HUGH H. STEELE *Gastroenterology*, 1949, 12, 225

Eleven cases of argentaffine tumors are reported. Eight of these occurred in the appendix and 3 occurred elsewhere in the gastrointestinal tract. Of the 8 patients in whom the tumor was located in the appendix, 5 were operated upon for acute appendicitis. In several of these cases the tumor probably acted as a fecolith producing occlusion of the lumen and subsequent edema and inflammation. Three patients had no symptom of appendicitis, the appendix having been removed as a routine procedure during other abdominal operations. In none of these cases was metastases, mitotic figures, or invasion of the muscularis found. Patients were followed for

an average of 5½ years without evidence of recurrence. Although there are several reported cases of malignant argentaffine tumors of the appendix, those in the present series are benign. It is possible that argentaffine tumors of the appendix cause symptoms of appendicitis and are removed before they have a chance to become malignant.

Of the 3 tumors which occurred in the intestinal tract elsewhere than the appendix, one involved the cecum and two, the ileum. All 3 lesions were malignant and had metastatic glands. These patients were operated upon and the lesions resected. Two patients died within 16 months of surgery, and 1 was alive 8 years after surgery.

Argentaffine tumors arise from Kulchitsky cells which are found in all parts of the gastrointestinal tract and are most numerous in the crypts of Lieberkuhn in the terminal ileum and appendix. They constitute about 8 per cent of all observed neoplasms of the small intestine. They most frequently occur in the terminal ileum and appendix, but may occur anywhere in the gastrointestinal tract. Occasionally they are multiple.

The incidence of malignancy of argentaffinomas occurring outside the appendix varies from 22 to 38.3 per cent in different reported series. The authors conclude that since some become malignant, all must be treated as such.

FREDERICK W. PRESTON, M.D.

Lymphosarcoma of the Gastrointestinal Tract, with a Report of 21 Cases M. A. SPELLBERG and SIMON ZIVIN *Arch. Int. M.*, 1949, 83, 135

The authors, in a review of their own material, found 1 case of lymphosarcoma to every 88 cases of gastric carcinoma in patients ranging from 26 to 57 years of age, and of an average age of 47 years. Emphasis is made that when a neoplasm is found in a younger patient, it is more likely to be a lymphosarcoma than a carcinoma.

By and large, the symptoms found with lymphosarcoma of the stomach tend to be nonspecific and somewhat ulcerlike, consisting of postprandial distress, belching, bloating, pain unrelieved by food, backache, and vomiting, weight loss was noted in 5 of 11 patients. Hematemesis or melena was noted in 6 of the 11 cases, and occult blood in the stool 7 times, frequently there was an associated anemia. It is believed that this bleeding feature has not been emphasized in the literature previously. In 5 cases an epigastric mass was palpable.

Roentgenography is of help diagnostically only infrequently. The usual diagnosis made is that of carcinoma, occasionally, the roentgen diagnosis is normal stomach or large rugal folds.

Gastroscopy is helpful but not infallible in cases of diffuse infiltration. The diagnostic difficulties are attributable to the morphology of the tumor, inasmuch as it so frequently produces a diffuse type of infiltration without the formation of localized defects.

Pathologically, the lesion is usually encountered on the greater curvature of the stomach. Involve-

ment of the perigastric lymph nodes was found in 8 of 11 cases, but no liver metastases were noted. Five of the lesions were the small cell type of malignant lymphoma, and 5 were the large cell or reticulum cell type. The prognosis was associated with the cell type of the lesion, the patients with the small cell type had an average survival of 44 months, whereas the 5 patients with the large celled, reticulum type had an average survival of only 7 months.

The opinion that there is a relatively favorable response to treatment of lymphosarcoma is not shared by all observers. In the literature the survival figures given vary from 6 6 months to 7 years. The authors state that their survival figures for lymphosarcoma are better than those for carcinoma of the stomach. They had a total of 3 "5 year cures" of lymphosarcoma.

Ten cases of localized intestinal lymphosarcoma were observed, 5 in the small intestine and 5 in the large intestine, giving an equal incidence in the small and large bowels for the series, although references can be found in the literature concerning the increased incidence of lymphosarcoma in the small intestine. About 1 lymphosarcoma was found to every 300 carcinomas in the large bowel and 1 lymphosarcoma was found to every 4 1 carcinomas in the small bowel.

The symptomatology of lymphosarcoma of the bowel varies with the location of the tumor, but it is stressed that an abdominal mass was palpated in 80 per cent of the cases, varying signs of obstruction were present but no blood in the stools was noted. No specific diagnosis was ever possible by means of roentgenography in these cases. As with gastric lymphosarcoma, there was absence of widespread metastases, however, intestinal lymphosarcoma appears to carry an extremely poor prognosis, as most of the patients died in less than 6 months.

JANE C. MACMILLAN, M.D.

The Vascularization of the Human Stomach. A Preliminary Note on the Shunting Effect of Trauma. A. E. BARCLAY and F. H. BENTLEY *Gastroenterology*, 1949, 12: 177

Using a technique of microarteriography described by Barclay in 1947, the authors studied the arterial circulation of the stomach wall in cadavers and in specimens of stomach resected for duodenal ulcer. In order to demonstrate the arteries and their branches down to the arterioles, a preparation of bismuth oxychloride was injected into one of the gastric or gastroepiploic arteries. The size of the particles in the preparation used was such that the capillaries were not outlined. In the submucous layer there is a plexus of arterioles so profuse that an injection through a single gastric or gastroepiploic artery suffices to fill the whole vascular plexus of both anterior and posterior gastric walls, and also the other gastric and gastroepiploic arteries by retrograde flow. To demonstrate small arterioles and capillaries a 10 per cent solution of colloidal silver iodide was used. By use of this material a second plexus of smaller ves-

sels close to the mucous membrane can be demonstrated. The capillaries which vascularize the mucous membrane arise from this plexus.

There was a striking difference between the microarteriographs obtained from cadaver specimens and in the resected specimens. In the former there was much more complete filling of the vessels of the mucosa. One stomach was obtained from a patient under high spinal anesthesia, and in this specimen the vessels of the mucosa also filled completely when microarteriography was done.

The authors conclude that arteriovenous anastomoses exist in the wall of the stomach in the region of the submucous plexus of vessels. The trauma incident to gastric resection causes these anastomoses to shunt blood away from the mucosa. However, the shunt mechanism is under the control of the sympathetic nervous system and when the sympathetic nerve pathways to the stomach are blocked the shunt remains closed.

Arteriovenous shunts similar to these demonstrated in the gastric wall have been demonstrated by Trueta in the kidney.

FREDERICK W. PRESTON, M.D.

Acute Perforations of the Stomach, and Small Bowel Ulcerations. CARLYLE AUGUST LUER *Surgery*, 1949, 25: 404

Between 1938 and 1948, 362 cases of acute, free perforations of gastrointestinal ulceration were seen at the St. Louis City Hospital. A detailed examination of their records forms the basis of this study. Many interesting points follow closely similar studies previously reported. Some statements of fact are particularly worthy of attention.

The operative mortality has gradually dropped from 1938 to 1948 and is possibly attributable to the use of sulfonamides and penicillin. However, it is particularly worthy of attention that the mortality climbed rapidly with the number of hours perforation was present before admission, thereby delaying surgical treatment.

From 0 to 6 hours the mortality was 10.6 per cent, from 6 to 12 hours, 25.4 per cent, from 12 to 24 hours, 52.0 per cent, and over 24 hours, 75.9 per cent. Thus the wisdom of early and good surgical management seems unchanged by the use of sulfonamides and antibiotics.

It is of interest that in 22 of the patients, perforation occurred while the patient was in the hospital, and all patients died. This is not an occurrence that is common only to this hospital, and the importance of careful and early evaluation of patients in the hospital who present acute abdominal symptoms is stressed.

The physical findings of a systolic blood pressure of 80 or lower, a low white count, subnormal temperature, and rapid respirations were ominous, followed by a high mortality.

Certain findings are important because of the high incidence of their occurrence in acute perforation. Pneumoperitoneum was demonstrated by roentgen

ogram in 63.5 per cent of cases in less than 6 hours and in 89.7 per cent in over 6 hours

"Boardlike" involuntary rigidity was present in 98.6 per cent of cases within 6 hours but was not so constant after the initial chemical peritonitis had subsided. Auscultation was done in two-thirds of the cases. Bowel sounds were absent in 79.2 per cent of patients and hypoactivity was observed in 13.8 per cent.

The conditions existing which were mistaken for acute perforations were, in order of incidence, appendicitis, acute cholecystitis, and acute pancreatitis. However, blood diastase levels were obtained in about two thirds of the cases of acute perforation and were normal in 97.5 per cent, the remainder were elevated between 600 and 800 units.

The author concludes that the duration of time from perforation to operation seemed to be the most important factor in influencing the prognosis. As time elapsed, increased soilage of the peritoneal cavity and bacterial infection occurred, and dehydration and electrolyte imbalance increased. Therefore, the most effective treatment consisted of correction or prevention of electrolyte imbalance, followed by surgery as soon as possible for closure of the perforation with an omental graft and closure of the incision without drainage.

FREDERICK C. HOEBEL, M.D.

Diverticula of the Stomach. A Report of 30 Cases and a Review of the Literature. CHARLES H. BROWN, ROGER P. BISSENETTE, and ROBERT D. ALBEE. *Gastroenterology*, 1949, 12: 10.

Studies were made of 30 cases of gastric diverticula. By far the most common location for gastric diverticula is in the cardia, and these are usually congenital in origin. Diverticula located outside of the cardia are frequently associated with other pathological lesions such as carcinoma, ulcer, aberrant pancreatic tissue, gall-bladder or pancreatic disease. There are no characteristic symptoms of the condition, and if symptoms are present they are usually caused by other conditions. In 7 of the 30 cases studied, the symptoms were thought to be due to the diverticula itself and consisted of ulcerlike distress. Gastric hemorrhages resulting from the diverticulum occurred in 2 cases. Conservative therapy utilizing an ulcer régime usually is sufficient to control the symptoms. Surgery was not necessary in any of the 30 reported cases. In cases coming to surgery (recorded in the literature), it is often very difficult to find the diverticulum. F. J. LESEMAN, JR., M.D.

Surgical Treatment of Peptic Ulcer in the Region of the Cardia (Zur chirurgischen Behandlung des cardianen Ulcus ventriculi). H. FINSTERER. *J. internal chir.*, Brux., 1949, 9: 1.

On the basis of an exceptionally wide experience in gastric surgery, the author, director of the surgical department of the University Hospital at Vienna, Austria, discusses the problems of peptic ulcer in the region of the cardia.

Ulcers near the cardia are not as rare as is generally assumed, among a series of 8,230 gastric resections for ulcer, the author observed 614 cases, i.e., about 20 per cent. This high percentage is partly explained by the difficulty of diagnosis and treatment. A number of interesting cases are described in which the ulcer was either mistaken for carcinoma or declared inoperable by other men, and in which surgery by the author resulted in complete cure.

Errors in diagnosis are frequent because the symptoms and signs are less characteristic than in pyloric ulcers. Frequently hypoacidity or anacidity are present rather than hyperacidity, and roentgen examination reveals less typical pictures. The ulcer is often mistaken for carcinoma, cardiospasm, or angina pectoris. Even at laparotomy, correct diagnosis is difficult when the ulcer is situated at the posterior wall, as it often penetrates into the lesser omentum or in the pancreas. Therefore, the author recommends in all cases in which an ulcer is diagnosed clinically but not found at operation, that a gastrotomy be made and the inside of the stomach explored with the bare finger, without rubber gloves. In this manner the ulcer is discovered easily, and no infection after digital exploration has ever occurred in the author's experience.

Resection of ulcers at the posterior wall should be done only if the ulcer is at least 1 to 2 cm. distant from the esophagus because sutures involving the esophageal wall are unsafe.

The author discusses in great detail the indications for, and techniques of, various operations. He rejects gastroenterostomy as valueless. The best results were achieved by pylorogastrectomy. In patients under 60 years with ulcers near the cardia, penetrating to the lesser omentum, the author performs the Billroth I operation with excellent results, he had no fatality in 109 patients treated by this method.

If an ulcer of the posterior wall involves the cardia, it is left in place and resection of the distal half of the stomach and the pylorus is performed after the method of Kelling-Madlener. If the length of the duodenum permits, a Billroth I operation or an anastomosis by the Hofmeister-Finsterer method is done.

This abstract can only give a perfunctory picture of this very interesting article which should be read in the original.

WERNER M. SOLMITZ, M.D.

Production of Gastric and Duodenal Ulcers by the Prolonged Administration of Mecholyl. J. WENER, H. L. HOFF, and M. A. SIMON. *Gastroenterology*, 1948, 11: 904.

Mecholyl (acetyl- β -methylcholine) is a choline ester which evokes an increased, more acid gastric secretion in dogs. When injected intramuscularly, in a beeswax and mineral oil mixture, it prolongs and increases continuous gastric secretion.

The observation that single injections of mecholyl in dogs produced a bloody diarrhea and postmortem findings of hemorrhages and erosions of the gastric

and duodenal mucosa, led the authors to investigate the effects of the drug. The effects of repeated injections of mecholyl were studied in two groups of dogs. In the first group, 29 dogs received daily injections of an aqueous solution of mecholyl subcutaneously. The dosage levels (determined by experience) were the maximum each dog could tolerate without collapsing or going into shock. Injections were made daily at 9 a. m., and the animals were not fed or given water until 4 p. m. The diet consisted of ground red beef and all animals were allowed free access to water after 4 p. m. Seven of the dogs were also given prostigmine along with mecholyl. All but one of the dogs died from the general effects of the drug.

In the second group of animals (19 dogs), the mecholyl was embedded in a beeswax and mineral oil mixture in order to prolong the effects of the drug. The drug was prepared according to the method devised by Code and Varco to prolong the action of histamine, it contained approximately 90 to 100 mgm of mecholyl per cubic centimeter. "Sub-shock" dosage levels were determined. The diet and feeding times were the same as for the first group. All but 4 of the dogs died from the general toxic effects of the drug, and the remaining dogs were sacrificed.

The experimental data are tabulated. Following the injections of mecholyl a sequence of pathological changes occurred which consisted of marked hyperemia and engorgement of vessels, interstitial mucosal hemorrhages with superficial necrosis, erosions, and acute or subacute ulcerations in the stomach and duodenum.

In nearly all instances, marked generalized parasympathetic responses accompanied every injection of mecholyl, and led to immediate collapse and death of the first few dogs, especially when prostigmine was injected together with the drug. This state of collapse was immediately relieved by the subcutaneous injection of atropine.

Mecholyl caused vomiting, frequently blood tinged, and occasionally massive hematemesis. It also caused increased gastrointestinal motility which, within 15 minutes, resulted in bloody diarrhea. This condition usually terminated in from 1 to 2 hours, and within 8 to 24 hours stools were formed, but tarry in color. In numerous instances gastrointestinal bleeding continued for 12 to 18 hours after injection, and finally such animals died as a result of extensive hemorrhages from the gastrointestinal tract.

Postmortem examination of the stomach usually revealed diffuse hyperemia, multiple mucosal hemorrhages, and areas of superficial necrosis and erosion. The hyperemic discoloration of the stomach was most severe in the fundic area, which was sharply demarcated from the paler, pyloric region. Beginning sharply at the most proximal end of the duodenum, the hemorrhagic involvement of the mucosa extended through the entire intestine with decreasing severity as the ileum was approached. Changes at

autopsy were most pronounced when death ensued shortly after an injection with mecholyl.

Histological examinations of the hemorrhagic areas of the stomach and duodenum showed marked dilation of the blood vessels, especially the capillaries, and the presence of acute diffuse interstitial hemorrhage into the mucous membrane, with necrosis of the most superficial layers of the mucosa. In a number of situations underlying a relatively intact mucous membrane in which interstitial hemorrhage had occurred, infiltration by acute inflammatory cells suggested a focal hemorrhagic gastritis or duodenitis.

The erosions were multiple, were usually confined to the fundic portion of the stomach, and were less often seen in the pylorus and duodenum. Most of the lesions were erosions, but a few dogs showed gastric or duodenal ulcers. Involvement of the deeper layers of the intestinal wall and the presence of an inflammatory ridge about the lesion were the criteria for ulcer.

Experimental data following the prolonged administration of mecholyl in beeswax are tabulated. The pathological changes in the stomach and duodenum were pronounced and lasted longer than in the dogs receiving mecholyl in an aqueous solution. No ulcers were found in the stomach or duodenum, although gastric or duodenal erosions were found in 8 of the 19 dogs injected.

Although the quantities of mecholyl injected with the beeswax were from 2 to 4 times greater than that given by subcutaneous injection of mecholyl in aqueous solution, the general parasympathetic responses to the drug were not as severe, and fewer dogs collapsed or died immediately after the injections than when aqueous mecholyl was given alone. Bloody diarrhea persisted much longer and led to the death of 7 of 19 dogs from severe gastrointestinal hemorrhages. The hemorrhagic appearance of the gastrointestinal mucosa was more extensive and more severe than in the first group of dogs given mecholyl alone.

The microscopic findings in the numerous sections taken from the gastrointestinal tract strongly suggest that vasodilatory action of mecholyl on blood vessels was the main factor in the pathogenesis of these lesions. It appears that the marked vascular engorgement and hyperemia gave rise to stasis, increased capillary permeability and tissue anoxia, which resulted in extravasations of red blood cells into the mucosa, and was followed by superficial necrosis of the mucous membrane erosions and eventually led to the formation of true ulcers. Additional factors, such as trauma, acidity, and malnutrition probably play a part in the genesis of the lesions observed in these experiments.

ERNEST D. BLOOMENTHAL, M.D.

Total Gastrectomy (Gastrectomia total) VOLTA BAPTISTA FRANCO *Rev. bras. gastroenter.*, 1949, 1, 7

Three total gastrectomies for cancer of the stomach were performed by the author.

SURGERY OF THE ABDOMEN

The first patient succumbed to the operative shock, the second patient died on the eighth postoperative day from peritonitis caused by a dehiscence of the suture line connecting the esophagus with the jejunum. The last person operated upon is still alive, 18 months after operation. This patient was in excellent condition for a period of 15 months following the removal of his stomach, then he began to experience difficulty in swallowing food. Roentgenograms showed a tumor in the distal portion of the esophagus. The patient's condition necessitated performance of a jejunostomy. Preoperative measures have been taken for transthoracic esophagectomy.

JOSEPH K. NARAT, M.D.

Malfunction of the Gastrojejunal Anastomosis during the Early Postoperative Period Following Gastrectomy (Les dysfonctionnements précoces de l'anastomose après gastrectomie) LUCIEN LEGER and JEAN LOYQUE J. chir., Par., 1949, 65: 116

This discussion is limited to the factors which prevent a good result from jejunostomy in the early postoperative course following the Pean type of gastric resection. These factors are classified under four headings: (1) inflammatory obstruction, (2) mechanical difficulty, (3) functional disturbances, and (4) nutritional difficulties.

A case is reported in which evidence of obstruction of the efferent loop became apparent on the fifth postoperative day following a gastric resection. Reoperation revealed a fibrinous type of peritonitis and dense adhesions posterior to the mesocolon had blocked the anastomosis. There was no leakage at the suture line or other apparent cause for the peritonitis. The authors cite several cases of other surgeries in which failure of the anastomosis to function was attributable to inflammatory causes of mechanical obstruction is retrograde invagination of the jejunum into the stomach. Other causes include incarceration of a loop of small intestine in the opening in the mesocolon, obstruction of the anastomosis by a mucus plug, and kinking of the efferent loop by a short mesocolon.

Certain cases of gastric dilatation following gastric resection appear to be on a functional basis. The authors postulate a reflex mechanism of which the splanchnic nerves constitute the motor inhibitory pathway. Splanchnic block often will relieve the condition and permit normal function to become established.

Resection of the pylorus in itself has the effect of reducing gastric peristalsis, which may be a contributing factor to postoperative gastric atony in some cases.

Reflux of the gastric contents along the proximal loop of the jejunum with subsequent dilatation of the duodenum and the stomach was encountered in 2 cases described by the author.

The longitudinal incision in the jejunum may interrupt peristalsis along this segment of bowel and thus prevent function of the anastomosis.

Edema at the anastomotic stoma on the basis of hypoproteinemia is another condition which may interfere with the proper evacuation of the stomach. However, the authors do not attribute much importance to this factor because hypoproteinemia cannot be demonstrated in many patients with postoperative retention.

FREDERICK W. PRESTON, M.D.

Intestinal Obstruction Indications For Surgical Treatment (Oclusion intestinal. Indicaciones del tratamiento quirurgico) RAMÓN FLORES LÓPEZ and ANTONIO LUNA OLIVARES Rev. gastroenter Mexico, 1949, 14: 1

Wangensteen's classification of intestinal obstruction is preferred by the authors to that of Ochsner, Calkins, and others.

Among other diagnostic measures the authors use peritoneal puncture. From the viewpoint of indication for surgical treatment, all patients with intestinal obstruction may be divided into 4 groups:

1. Patients who require immediate surgical intervention because of a strangulated external or internal hernia, mesenteric thrombosis or embolus, volvulus, acute intussusception, strangulation caused by intestinal atresia, imperforate anus, or congenital diaphragmatic hernia.

2. Patients in whom the operation may be postponed from 18 to 24 hours to allow improvement in the general condition and the institution of decompression of the intestines. To this group belong certain patients with strangulation of the colon, obstruction caused by adhesions, or acute episodes of chronic intestinal intussusception.

3. Patients in whom the operation may be postponed for several days while decompression is being employed. To this group belong patients with an obstruction of the gut by a stone or intestinal parasites, or with ileus caused by compression of the gut (by adhesions or bridges), peritoneal abscess, or by perivisceritis.

4. Patients with functional ileus, either spastic or paralytic. This group does not require any surgical intervention.

As a rule, the authors prefer spinal anesthesia, particularly the fractional method. For patients in a poor general condition and with marked hypotension, general anesthesia with a closed circuit is employed. If spinal anesthesia is used, it is important to administer oxygen through a nasal catheter. If the Levin tube is not inserted before the operation, gastric lavage is indicated preoperatively, to prevent aspiration of the gastric contents into the respiratory tract.

If an external strangulated hernia is present, the incision is made over it. In other cases the x-ray findings may furnish information as to the desirable site of incision. If the location of the lesion cannot be established before the operation, a right lower paramedian incision is made. If the obstruction is located in the lower portion of the small intestine, a right paramedian incision is made, one-third of it being located above, and two-thirds of it below, the

umbilicus If the obstruction is in the upper portion of the small intestine, a left paramedian incision is made, with two-thirds of it above, and one-third below, the umbilicus

A subcostal incision is employed for the treatment of a diaphragmatic hernia, the abdominal approach being used exclusively. Paramedian incisions are used for the treatment of obstructions of the large intestines

The authors do not recommend transverse incisions because they are more time-consuming and cause more bleeding. Longitudinal incisions are exposed to lesser tension, produce less postoperative pain, and are more reliable as far as prevention of postoperative disruption of the abdominal wall is concerned

The authors prefer a side-to-side anastomosis to a terminolateral or end-to-end anastomosis

Patients with volvulus of the intestines or a mesenteric infarct require a relatively large amount of blood for transfusion

The Mikulicz method is employed only in selected cases of ileus of the large intestines, such as volvulus of the sigmoid or of the cecum, with gangrene, or carcinoma of the colon with perforation or irreducible intussusception

If multiple strictures of the small intestines, caused by tuberculosis, mycotic processes, or nonspecific granuloma, are encountered, or if an extensive cancer or numerous postoperative adhesions are found, a short circuit is established by means of an intestinal anastomosis

Enterostomy is done only in patients with carcinomatosis or tuberculosis, if the general condition is grave. The procedure is useless in paralytic ileus

Colostomy is employed in patients with ileus of the large intestines caused by cancer, diverticulitis, granuloma, or constricting pericolicitis

Sulfanilamide in saline solution is used intraperitoneally before closure of the abdominal wall. Penicillin and streptomycin are given parenterally

The authors stress the value of the Wangenstein tube for the treatment of selected cases of intestinal obstruction

JOSEPH K. NARAT, M.D.

Primary Malignant Disease of the Small Bowel

DAVID STANLEY LIKELY, JAMES R. LISA, MELVIN H. STITCH, and H. D. STEIN. *Arch. Int. M.*, 1948, 82, 206

The authors give an excellent review of the literature concerning malignancies of the small bowel. In addition, they present 17 cases recently encountered, from which they draw the following conclusions

Carcinoma of the small bowel comprises about 3 per cent of the gastrointestinal carcinomas and is much less common than carcinoma of the large bowel. Not including this series, there have been reported only about 365 cases of carcinoid, or argentaffinoma tumors, of the small intestine. Lymphosarcoma, in contrast to carcinoma, is observed more commonly in the small than in the large bowel according to the literature. There are about 149

reported cases of lymphosarcoma of the small intestine including those of the authors

The prognosis is considered poor in carcinoma and lymphosarcoma, and good in carcinoid

Clinically, one of these rare tumors may be suspected in the presence of mild unexplained nausea, intermittent obstruction, and mild anemia

JANE C. MACMILLAN, M.D.

The Surgical Therapy of Duodenal Ulcer

JOHN H. GARLOCK and ALBERT S. LYONS. *Surgery*, 1949, 25, 352

The authors present a review of 187 cases of duodenal ulcer. All patients were subjected to partial gastrectomy in the private practice of the senior author. The usual indications for surgery formed the basis for selection of patients. These were failure of a medical regimen to control the disease, repeated hemorrhages, perforations, and obstruction due to scarring. The authors are of the opinion that the only indication for gastroenterostomy in duodenal ulcer is the presence of a benign obstruction accompanied by a low acidity in an elderly patient

Usually, two-thirds of the stomach are removed. It is emphasized that the greatest care must be taken to completely remove the pyloric antrum and pyloric ring and, in the vast majority of cases, this means that the ulcer-bearing portion of the duodenum must be removed. It is the authors' belief that with careful, meticulous dissection this can be accomplished in almost 100 per cent of the cases, and in this series only one exclusion operation of the Finsterer type was performed. This patient developed a gastrojejunocolic fistula 6 years later. If the surgeon is positive that he can remove the pyloric ring, and if the ulcer is located at the bed of the first portion of the duodenum or in the second portion, then there is no harm in leaving the ulcer behind provided a good closure of the stump can be made. The author favors a Hofmeister retrocolic type of anastomosis. If extensive retroperitoneal dissection has been done in the region of the duodenum or pancreas a drain is always inserted

The author believes that vagotomy should be performed as well as a partial gastrectomy in those cases in which there is a marked hyperacidity or recurrent hemorrhages. Vagotomy alone is of value in gastrojejunal ulcers following adequate partial gastrectomy

There were 4 deaths in this series of 137 patients, an operative mortality of 2.1 per cent. There have been only 4 cases of recurrent ulceration, in 3 of these an adequate partial gastrectomy had been performed, and in the fourth case an exclusion operation had been done

F. J. LESEMANN, JR., M.D.

Necrotic Jejunitis

K. A. FICK and A. P. WOLKEN. *Lancet*, Lond., 1949, 1, 519

The clinical features, diagnosis, treatment, and pathology of an endemic necrotic jejunitis are described. Two cases among 18 under observation are described in detail

Necrotic jejunitis is believed to be initiated by defects in the diet. The 18 cases occurred in 13 men and 5 women. Their average age was 61 years. Sixteen died with an average duration of 7 days of illness. Two patients in whom a wide resection of the jejunum was carried out lived.

Recent work suggests that the *Clostridium* "enterotoxigenus," or *Clostridium welchii*, type F, plays an important part in the causation of jejunitis.

RICHARD J. BENNETT, JR., M.D.

Volvulus of the Cecum EDUARD MELCHOIR. *Surgery*, 1949, 25: 251.

Of 6 patients with volvulus of the cecum, 5 were treated by primary resection of the twisted bowel. All of these recovered, although in one patient the condition was complicated by gangrene and peritonitis. In a still more severe case the patient did not sustain the nonradical intervention. On the whole these results are better than those generally obtained in distortion, with or without cecostomy and/or cecopexy. Nonradical operations expose the patient to the danger of recurrence. Primary resection is, therefore, the preferred treatment in this emergency. The possible use of emetine as a supplement following operation should be considered.

CHARLES BARON, M.D.

Volvulus of the Cecum, with a Review of 100 Cases in the Literature and a Report of 6 New Cases J. L. DONHAUSER and S. ATWELL. *Arch Surg*, 1949, 58: 129.

The previous literature reviewed by the authors revealed many pertinent facts. The incidence of volvulus of the cecum is about 1 per cent of the cases of intestinal obstruction in this country, but it is higher in Central Europe and in Russia.

Torsion or volvulus of the cecum has been defined as a condition in which there is torsion limited to the cecum, ascending colon, and adjacent portion of the small intestine. Hyperfixation of the hepatic flexure, ascending colon, or terminal end of the ileum, and hyperdescent of the cecum are contributing factors to torsion of the cecum, but the essential anomaly is hypofixation of the cecum. Torsion, when it occurs, is commonly from 180 to 360 degrees, but it may be as much as 720 degrees.

Dietary measures are probably contributory and are thought to explain the high incidence in Central Europe and Russia. The incidence is higher in those who have had previous peritoneal damage.

Roentgenologic interpretation is difficult except that it confirms an intestinal obstruction. A barium enema is of value when the column of barium cannot pass a certain point in the colon and thus the cecum is not defined although a large collection of gas appears at the site of the cecum.

A flat plate on admission and another after 24 hours of intestinal drainage by suction are significant if the last one looks the same as the first or if the localized gas collection is slightly larger than in the first one. It suggests closed loop obstruction.

The signs and symptoms are abdominal. The onset is usually slow but there is no definite sign or syndrome. The findings of intestinal obstruction are present some time after the onset of the symptoms.

The authors summarized 100 cases in the literature. Torsion in this group occurred at any age, but in 50 per cent of the cases it occurred between the ages of 20 and 45. Women and men were equally susceptible. The signs and symptoms usually were those of obstruction. There was considerable distention and a mass was often palpable.

Predisposing factors were pregnancy, previous operation, high roughage diet, strong catharsis, dietary indiscretions, and unusual exertion.

The mortality rate is high and is unaffected by the type of operation. However, early operation will definitely lower the mortality.

FREDERICK C. HOEBEL, M.D.

Myenteric Plexus in Congenital Megacolon: Study of 11 Cases FRANCIS R. WHITEHOUSE and JAMES W. KERNOHAN. *Arch Int M*, 1948, 82: 75.

On the basis of theoretical and experimental observations, it was the feeling of the authors that one approach to the study of the etiology and pathogenesis of congenital megacolon would be the study of the myenteric plexus (plexus of Auerbach) of the colon in cases of congenital megacolon in which postmortem examination had been performed. The myenteric plexus apparently has as its main function in the colon the conduction of stimuli and the co-ordination of movements and, as a result of such function, would be of importance in any consideration of the pathogenesis of congenital megacolon.

The myenteric plexus was studied by the authors in 11 cases of congenital megacolon, a series of cases used as controls, and 5 cases of secondary megacolon.

The myenteric plexus was found to be absent in the most distal part of the colon in all cases of congenital megacolon. In 80 per cent of the cases the myenteric plexus was absent also in the "transitional region." In 60 per cent of the cases the myenteric plexus was also absent in the lower part of the sigmoid. In 20 per cent of the cases the absence of the myenteric plexus extended from the rectum into the upper part of the sigmoid and descending colon.

In all cases of congenital megacolon there were nerves present in the location of the myenteric plexus which were not seen in the control cases.

The strategic location of these changes, a review of previous theoretical concepts, experimental production, and certain physiologic and anatomic studies pointed toward the significance of the changes in the myenteric plexus in the pathogenesis of congenital megacolon.

Surgical Treatment of Cancer of the Colon (La terapia chirurgica del cancro del colon) CARLO SPANGARO and ANTONELLO FRANCHINI. *Arch Ital Chir*, 1949, 71: 17.

The authors analyze their results in the treatment of cancer of the colon. They include 146 patients

seen from 1932 to 1946. There was a slight majority of males. The ages varied from 30 to 84 years, with the highest incidence in the sixth and seventh decades.

Radical treatment was used in 66 cases, or 45.2 per cent. In 59, or 34.2 per cent, palliative measures were employed. Thirty, or 15 per cent, of the cases were inoperable. The cecum and transverse colon were most often amenable to radical resection, while the sigmoid and hepatic flexure were least often amenable to this procedure.

A right hemicolectomy was performed on 23 patients with a mortality of 43 per cent. Mikulicz resection was performed on 37 with a mortality of 24 per cent, and intraperitoneal segmental resection was performed on 6 patients with 4 deaths, a mortality of 66 per cent.

Palliative measures consisted of 28 colostomies on the right side with 9 deaths, and 20 colostomies on the left side with 1 death.

The most frequent cause of death was peritonitis. Only 2 cases of shock were seen. The most frequent cause of peritonitis was failure of the suture line to hold.

Among the complications, obstruction was the most common, being seen in 68 per cent of the cases and most often on the left side. This complication is considered to be a manifestation of an advanced process.

A study of the results showed that hemicolectomy resulted in a definite cure in 49 per cent of the patients, with 8 per cent showing metastasis in 2 or 3 years. The Mikulicz procedure resulted in cure in 51 per cent of the patients with evidence of metastasis or recurrence in 25 per cent in 2 or 3 years. The authors believe that any patient who lives for 3 years after operation should be considered clinically cured.

LUCIAN J. FRONDUCCI, M.D.

Wounds of the Colon and Rectum—A Critical Analysis of Current Methods of Surgical Treatment with Emphasis on Details of Surgical Technique. LEWIS S. PILCHER. *Mil. Surgeon*, 1949, 104: 188.

The author reviews the details of surgical technique which his extensive war experience demonstrated to be most effective in the treatment of wounds of the colon and rectum. While, in general, some form of exteriorization colostomy is the method of choice in the treatment of wounds of the colon, small single perforations of the colon may, on occasion, be closed by simple suture. Wounds of the rectosigmoid and rectum must be closed by suture, and a proximal diverting colostomy performed. For most wounds, tangential exteriorization or loop colostomy is the treatment of choice. Great care must be taken not to overlook a posterior or mesenteric perforation. Extensive injuries of the right colon are best treated by resection of the entire right colon with ilio-transverse colostomy. The author does not believe that under wartime conditions the Lahey-Mikulicz technique of a double-barreled ileo-

colostomy is a satisfactory procedure. In any type of exteriorization procedure, great care must be exercised to prevent the colostomy opening from retracting below the skin level.

Under wartime conditions the Mikulicz spur colostomy did not prove entirely satisfactory. Loop colostomies proved to be more satisfactory and their closure could be carried out either extraperitoneally or intraperitoneally. If closed extraperitoneally, great care had to be taken to completely free the bowel from the transversalis fascia in order to avoid deformity and angulation, if performed intraperitoneally, care must be exercised not to suture through edematous bowel. Open methods of suture were preferred to aseptic anastomoses.

Intraperitoneal wounds of the rectosigmoid should be treated by suture and proximal diverting colostomy. Wounds of the extraperitoneal rectum and anus should be similarly treated, and the author stresses the need for suture of such wounds.

F. J. LESEMAN, JR., M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Pseudoscirrhus Carcinosis of the Liver (Carcinosis pseudoscirrosa del fegato). MARIO ALBERTO DINA. *Arch. ital. mal. app. diger.*, 1949, 15: 113.

The author describes 2 cases of cirrhosis of the liver with metastasis from an adenocarcinoma of the pancreas and from an adenocarcinoma of the ampulla of Vater. The clinical, and especially the anatomical characteristics of the disease present a peculiar picture which differentiates the condition from known neoplastic diseases involving the liver.

Macroscopically there was cirrhosis with major or minor reduction of the size, and with large fibro-lardaceous and variegated interstitial bands. Histologically, there were isolated neoplastic tubules or cords invading the fibrous connective tissue. These were found in lacunae with endothelial walls, with invasion of the pseudolobular parenchyma from the periphery and the center.

The author proposes the theory of an endolymphatic infiltration of a secondary neoplasm in a previously cirrhotic liver. This would explain the scirrhus nature of the neoplasm which was absent at the site of origin.

LUCIAN J. FRONDUCCI, M.D.

Parasitic Cholecystitis (Colecistitis parasitaria). JOSÉ OVIEDO BUSTOS. *Prensa med. argent.*, 1949, 36: 33.

Bustos believes that in the presence of a cholecystitis, particularly in the absence of stones, and in cases in which there is an associated zooparasitosis, the latter must be ruled out before other biliary factors are considered. In over 40 cases the following organisms have been found as primary or secondary invaders of the gall bladder: *Lamblia* or *Giardia* intestinalis, *Fasciola hepatica*, *Ascaris lumbricoides*, *Endamoeba histolytica*, *Hydatidosis*, *Taenia solium*, *Ankylostoma duodenale* or *Necator americanus*. Considerable speculation is recorded concerning the

pathogenesis and mechanics involved in the parasitic invasion of the bile reservoir, whether or not the entrance was effected by an ascending or descending route through the canalicular or biliary ducts, through the liver, peritoneum, blood, or lymphatic systems

Treatment primarily is directed against the parasites, and the specific for each type should be employed. If, during biliary surgery, the parasites are discovered, the antiparasitic drug should be introduced directly into the bile passages and into the duodenum

STEPHEN A. ZIEMAN, M.D.

Cholecystitis Emphysematosa EDWARD E. JEMERIN
Surgery, 1949, 25 237

Cholecystitis emphysematosa is an inflammation of the gall bladder with grossly discernible gas formation. It is a rare condition, although possibly not quite as rare as the small number of reported cases would indicate. Despite the fact that the first cases in which gas was found in the gall bladder were described by Stolz in 1901, only 14 additional cases have appeared in the literature since that time.

Pathologically, emphysematous cholecystitis is an acute, usually gangrenous, inflammation of the gall bladder wall with bacteria growing in the wall and producing gas. The wall crepitates and foamy fluid can be expressed from it. The lumen of the organ fills with infected fluid and gas accumulates there as well, replacing the fluid contents partially or entirely. Destruction of the wall with extension of infection outside the gall bladder is quite common, so gas-producing pericholecystitis is also to be expected.

The clinical picture is that of a severe acute cholecystitis, with pericholecystitis in a high percentage of the untreated cases. A characteristic shadow on the plain roentgen film of the abdomen makes the diagnosis. Usually, during the first 24 to 48 hours no gas can be seen. There then appears the dark, pear-shaped shadow of gas outlining the usually distended gall bladder with the wall of the organ demarcated by contained gas as a darker circumferential shadow. Stones may be visualized as positive or negative defects within the gas. A fluid level should not be uncommon in films taken in the upright position. Within a few days the gaseous collection within the wall may become broader and stratified, and streaks or blobs of gas may be seen in the surrounding tissues, indicating extension of the infection into the pericholecystic area. The biliary ducts and radicals are not customarily outlined by gas.

Treatment should be surgical, but not all authors are in agreement with this point of view. Whether surgery should be done in the acute phase or in the interval is a moot point in ordinary gall bladder surgery and cannot be decided conclusively for this variety of acute cholecystitis either. It would seem that if chemotherapy will control the acute infection it would be wise to wait until this has subsided. However, with evidence of beginning spread beyond the confines of the gall bladder, prompt surgical

intervention would seem to be the logical course to follow. Cholecystectomy is the operation of choice and should be performed whenever the general condition of the patient and the local findings will permit. Chemotherapy should, of course, be used in conjunction with surgery.

A case of cholecystitis emphysematosa is reported. This case of clinical acute cholecystitis with pericholecystitis showed the typical roentgen features of emphysematous infection. Gas was seen to fill the lumen of the gall bladder, to outline the wall, and to extend into the surrounding tissue. Because of uncontrolled diabetes and congestive heart failure, the immediate therapy was conservative. Apparent clinical subsidence of the acute phase was achieved. Operation was performed after 2 weeks, at which time the diabetes and cardiac status were well controlled, the patient was afebrile, and the abdominal signs had disappeared. Empyema of the gall bladder and pericholecystic abscess containing gas under tension were found. *Clostridium oedematiens* in pure culture was obtained from the pus. The gall bladder was necrotic and contained stones, one of which was impacted in the cystic duct. A right subphrenic collection was also found. The gall bladder was removed, and the subhepatic and subphrenic spaces drained. The postoperative course was entirely smooth for 10 days, the wound healing per primam and the operative site remaining soft and nontender. A chill with high fever occurred on the tenth day with a blood culture positive for *Bacillus coli*. Penicillin therapy was started immediately and within 2 days the temperature was normal. However, on the thirteenth day a severe cerebral accident occurred. The patient developed oliguria and lapsed into coma from which she never roused, and died on the twenty-fourth day after operation. Left ureteral obstruction with pyonephrosis was found at autopsy, and probably accounted for the transitory *Bacillus coli* bacteriemia. The operative site was clean and death was attributed to the cerebral accident.

CHARLES BARON, M.D.

Observations on the Technique of Subserosal Cholecystectomy (Bedeutung der Technik der subserösen Cholezystektomie) R. DEMEL
Wien med Wschr, 1949, 99 23

The author recommends that the operation of cholecystectomy be performed in a retrograde fashion commencing at the junction of the cystic and common ducts and proceeding toward the fundus of the gall bladder. In this manner injury to the common duct or hepatic artery, as well as to the liver, is prevented. Also, hemostasis is secured by the control under direct vision of the several blood vessels bridging the space between the liver and the gall bladder.

Normal saline solution is injected beneath the serosa along either side of the gall bladder so that the subserosa is distended with fluid. The serous coat can then be incised without injury to either the gall bladder or the liver. The serosal cuffs, preserved by

the procedure, are sutured together to reperitonealize the gall bladder fossa. If the cuffs of serosa cannot be preserved the liver may be approximated over the raw gall bladder fossa with interrupted sutures.

The author insists upon the use of a simple rubber tube for drainage of the operative area. The tube usually is removed within 4 to 6 days.

The technique of subserosal retrograde cholecystectomy is applicable for both acute and chronic cholecystitis, with or without stones, as well as for empyema or perforation of the gall bladder.

ORVILLE F. GRIMES, M.D.

The Surgical Problem of Periapillary Cancer

GEORGE T. PACK and ROBERT J. BOOHER *Arch Surg*, 1948, 57, 71

The authors present their experiences in 5 cases of periampullary cancer in which the radical operation of pancreaticoduodenectomy was performed. They believe that the presence of neoplastic biliary obstruction necessitates surgical attack on the biliary duct system, the pancreas, and the duodenum. Metastasis occurs in less than 25 per cent of the cases of periampullary cancer, and death usually occurs as a result of interference with the flow of bile. Almost two-thirds of cancers of the duodenum are periampullary.

Suprapapillary and intrapapillary cancers of the duodenum do not cause early symptomatology, as do periampullary tumors, and therefore the rate of operability is not as great, and metastases are more likely to have developed by the time that patients come to surgery. The results of surgery are also better in periampullary tumors than in other carcinomas of the duodenum and of the pancreas.

The development of the radical operation of pancreaticoduodenal resection with choledochojunostomy, pancreaticojejunostomy, and gastrojejunostomy by Whipple and others is described. A growing tendency toward standardization of the operation is apparent.

In the group of 5 patients whose cases are presented the symptoms were gradual in onset. The predominant symptom in 4 of the patients was painless jaundice and itching, and in the remaining case the early complaint was epigastric pain, which was followed by intermittent jaundice. This is in contrast to other reports of cases in which pain was an outstanding early symptom in many of the patients. All 5 of the authors' patients had insidious anorexia with loss of weight, and 2 patients had enlarged livers and distended gall bladders. All patients presented a distended gall bladder and common duct at operation, and this indicates the value of Courvoisier's law to the surgeon. Chills and fever occurred in one patient, this is not unusual. Melena occurred in 2 patients and severe secondary anemia in 3 patients (including the 2 with melena). This signified an ulcerating duodenal lesion which, when associated with obstructive jaundice, would indicate an ulcerated peripapillary tumor.

The diagnosis was difficult in the absence of jaundice, and particularly so when the carcinoma occurred in the pancreas. Awareness of the condition is therefore a necessary first step toward the diagnosis, as most cases begin with malaise, chills and fever, gastrointestinal symptoms, loss of weight, anorexia, and weakness. A palpable mass is an important physical finding. Roentgenologic studies were helpful in 2 of the 5 cases. Laboratory studies were not of great value in this series because of the variable stages at which the patients presented themselves.

When the diagnosis of obstructive jaundice is made, early surgery is indicated if a good resectability rate is to be attained with a long survival rate. The survival rate is very low for patients who have been ill for as long as 6 months before operation.

The difficulty of diagnosis at the operating table has been demonstrated by the fact that some patients in whom resection is done for carcinoma prove to have pancreatitis, and other patients with conditions diagnosed as pancreatitis are found at later operations to have carcinoma.

In the authors' cases the outstanding complication was pancreatic fistula, which occurred in 3 cases in spite of ligation of the pancreatic ducts and careful closure of the stumps. This indicates the wisdom of performing a pancreaticojejunostomy. Ascending cholangitis was prevented by placing the biliary gastrointestinal anastomosis at a good distance proximal to the gastroenterostomy.

The article is accompanied by roentgenograms, microscopic slides, and schematic drawings of the operations performed. Four radical pancreaticoduodenectomies and one local excision were performed. One patient survived for 3 years after operation and another, whose cancer was still resectable 2½ years after onset, is still living after 4 years. One death, 3½ months after operation, was the result of biliary and pancreatic fistula. One patient is alive and apparently well 1 year after operation, and 1 patient had recurrence 9 months after operation. ERNEST D. BLOOMENTHAL, M.D.

Chronic Recurrent Pancreatitis: Clinical and Laboratory Aspects. Serial Serum Diastase Levels Following Prostigmine Stimulation. WILLIAM A. KNIGHT, JR., R. O. MUETHER, and ANNE J. SOMMER. *Gastroenterology*, 1949, 12, 24

The authors review 58 cases of chronic recurrent pancreatitis. The most common symptoms were upper abdominal pain, weight loss, malaise, nausea, vomiting, food intolerance, anorexia, constipation, and weakness. Occasionally a low grade fever lasting for months was the presenting symptom. Hematemesis or melena occurred in 23 per cent of the cases. Pain is an almost constant feature of chronic recurrent pancreatitis and may be epigastric in location, referred to the back, or to either upper quadrant. Physical findings were inconstant and minimal. Mild upper abdominal tenderness was usually present.

The most helpful laboratory test was the serum diastase level which was found to be elevated in 64 per cent of the cases. Extremely low serum diastase levels may be seen in far advanced pancreatic disease. The glucose tolerance test, serum cholesterol, and stool examinations are of little aid in the diagnosis of chronic recurring pancreatitis.

In an effort to devise a more accurate laboratory test for chronic recurrent pancreatitis, a study was made of the response of the serum diastase levels of patients with normal and diseased pancreas to prostigmine methylsulfate. In the control series the serum diastase values showed very little variation following the injection of prostigmine methylsulfate, however, in 41 cases with chronic pancreatic dysfunction serial serum diastase levels following injection of the drug demonstrated significant changes in the diastase levels.

In general, the variations in patients with this disease may be classified into four types: in the first type a high fasting diastase level was present and following injection of the drug there was a progressive fall in the level, the second type of response was an initial rise followed by a progressive fall, the third type of response was a progressive rise following prostigmine stimulation, and the fourth type of response was in those patients who initially had a low diastase level, and in whom there was but little change following the prostigmine stimulation. The authors believe that the response of the serum diastase levels to prostigmine stimulation is a worthwhile test in patients with chronic pancreatic disease.

F J LESEMANN, JR., M D

Carcinoma of the Pancreas HOWARD K. GRAY *Arch Surg*, 1948, 57 763

In the preface of his exhaustive work on the surgery of pancreatic tumors, Brunschwig has stated that the pancreas has been regarded as the "hermit organ" from the surgeon's standpoint because of the rarity with which operations have been performed on it and because surgeons have been reluctant to undertake such procedures, often fearing the development of acute pancreatitis as a complication of the operation itself. The complexion of this dismal situation has changed rapidly, however, in the last 15 years, owing to the abundant information that has accumulated relating to diagnosis, preoperative and postoperative care, and surgical technique. Not the least factor has been a willingness on the part of many surgeons to challenge and to conquer this natural aversion to direct surgical attack on the pancreas and, by so doing, to demonstrate that partial, and even total, pancreatectomy can be done without imposing undue risk.

It has been stated that two main types of pancreatic carcinoma are observed: (1) cylindric cell carcinoma, arising from the ducts, and (2) carcinoma simplex, arising from the parenchyma.

It is ironical that carcinoma of the head of the pancreas should become manifest in many instances when the lesion is small enough to permit complete

surgical excision, and yet be so placed that it may be extremely difficult, if not impossible, to make a positive diagnosis. This refers in particular to small carcinomas of the head of the pancreas that produce extrinsic pressure against the terminal portion of the common bile duct and produce obstructive jaundice. The terminal portion of the common bile duct descends along the posteroinferior aspect of the bend joining the first and second parts of the duodenum and then along the inner side of the second part, where it is surrounded more or less by the head of the pancreas. Because of this anatomic arrangement, any attempt to obtain tissue for microscopic examination will entail a rather extensive surgical procedure unless the surgeon is fortunate enough to withdraw sufficient malignant tissue by exploring the common duct from within. It is rare that a specimen of the desired tissue can be obtained for biopsy in this manner in the early stages of obstruction because infiltration of the walls of the common bile duct by cancer will not have occurred, and the examining scoop or tissue extractor will encounter only a duct that is compressed from external pressure. It is also ironical that carcinoma of the body or tail of the pancreas (where surgical removal could be accomplished with the least difficulty and risk) should become manifest in many instances when the lesion is so extensive that complete surgical excision is not possible.

Although there is no method whereby the surgeon can accurately recognize the presence of a malignant lesion of the pancreas, much valuable information can be obtained from a carefully taken history and from the results of physical and laboratory examinations.

Pain of some character has been noted by practically all observers in the majority of cases.

When the lesion involves the head of the pancreas (approximately 75 per cent of cases), jaundice will be present in practically all cases. The nature of this jaundice may give an invaluable lead as to the underlying pathologic condition, for it is usually marked and constant. The remissions that are seen so commonly associated with stone in the common bile duct are absent, and because of the depth of the jaundice (occasionally as much as 60 or 70 mgm of bilirubin may be observed in 100 cc of serum) pruritus is marked and many factitial areas may be seen on the skin.

The presence of jaundice and a distended gall bladder may suggest obstructive jaundice due to carcinoma of the head of the pancreas or of the bile ducts below the orifice of the cystic duct, but this combination is by no means pathognomonic. The presence of deep, persistent jaundice, continuous acholia and a distended gall bladder may be considered a more reliable diagnostic complex.

Cachexia and loss of weight usually are symptoms of advanced carcinoma and in most instances will be present in a patient in whom the malignant condition has progressed to the point at which surgical excision of the lesion is no longer possible.

Laboratory data are of inestimable value, particularly in the presence of jaundice

Appreciable elevation of the content of lipase in the serum was noted in about 37 per cent of a series of cases of pancreatic cancer. Because this phenomenon probably was due to obstruction of the pancreatic ducts and/or associated pancreatic inflammation, it was thought to be significant in the diagnosis of cancer of the pancreas.

Studies of hepatic function show no remarkable deviation from that seen in obstructive jaundice arising from other causes, except perhaps in degree, for alteration of hepatic function is dependent on damage to the parenchyma of the liver.

The recognition of carcinoma of the islands of the pancreas may present an insoluble diagnostic problem, for it is well known that even though surgical exploration of the pancreas is carried out, an adenoma or carcinoma of the islet cells is not always demonstrable and definitely incriminated as the cause of a patient's spontaneous hyperinsulinism and associated hypoglycemia.

Although occasional instances of hypoglycemia undoubtedly are hepatogenic, the minimal reduction of sugar in the blood in itself rarely causes symptoms, and therefore the spontaneous occurrence of the clinical syndrome ascribed to hypoglycemia should make the physician acutely aware of the possibility of a benign or malignant islet cell tumor.

In review of the records of patients suffering from this unusual disease, it is interesting to note that an appreciable number of patients will be familiar with the fact that sugar will abort an attack, and have become accustomed to carrying candy or sugar with them at all times. The attack of hypoglycemic coma may be mistaken for drunkenness by the average layman, and it has not been an unusual experience to find that a patient has been discharged from his position on the mistaken assumption by his employer that he had been imbibing too freely.

Surgical treatment would seem to be indicated in practically all cases in which the presence of a carcinoma of the pancreas has been recognized, if for no other reason than to offer palliative relief from a condition that is unbearable. In view of the fact that the majority (60 to 70 per cent) of malignant tumors of the pancreas are situated in the head, and that most of these produce complete and persistent jaundice, the surgeon is justified in attempting to restore the flow of bile into the stomach or intestine if it is seen that radical removal cannot be effected.

Should there be any uncertainty as to the diagnosis, a period of observation may be indicated in order to permit determination of the general course of the disease.

The patient who is suffering from the hepatogenous type of jaundice is more likely to be harmed than benefited by operation.

In the absence of jaundice, the diagnosis of carcinoma of the pancreas is extremely difficult to make, and therefore the indications for surgical intervention are obscure. The decision to explore will

have to be made when other diagnoses have been discarded through a careful process of elimination. It is probable that more patients should undergo exploratory operations than are being operated on at present, for by such a course it will be possible to attack the disease when it is still amenable to surgical removal.

The author discusses preoperative preparation, and operative and postoperative treatment.

Role of Splenectomy in Thrombopenic Purpura
GEORGE BOGARDUS, J. GARROTT ALLEN, LEON O. JACOBSON, and CHARLES L. SPURR. *Arch Surg*, 1949, 58, 16.

Clinical data based on 20 cases of idiopathic thrombopenic purpura are presented. Ten of the patients in this group were treated medically, and 10 were subjected to splenectomy. Seven of the 10 patients treated medically were known to have had no recurrence for a period of from 6 months to 2 years. Five of the 10 splenectomized patients had a recurrence, in 2 of these it was severe. Of the patients who had a recurrence, 3 had the acute disease and 2 had chronic disease. Opinions concerned with the pathologic processes in thrombopenic purpura are discussed. The importance of the capillary abnormality, as well as the low platelet count, is emphasized. It is possible that the condition of the entire reticuloendothelial system, and not of the spleen alone, determines the course of the disease.

BENJAMIN GOLDMAN, M.D.

Fever Following Splenectomy (La febbre degli splenectomizzati) LUIGI TORRACA. *Gior ital chir*, 1948, 4, 675.

The author discusses fever following splenectomy. In certain cases a mild fever, which cannot be explained on the basis of infection or absorption, is present for several weeks. He analyzes 8 cases following splenectomies which he performed. Two patients had fever for more than 2 weeks. This represents 25 per cent, comparable to the 27 per cent reported by Saarenmaa of the Helsinki Clinic.

Among the theories which are discussed as to the cause of the fever are the following: (1) ligation of the tail of the pancreas, (2) formation of exudate in the operative area, and (3) collection of blood in the splenic bed. Other theories are mentioned.

The author concludes that all these theories are merely hypotheses which do not adequately explain the cause of the fever. He agrees with Tansini in considering it a problem which is still to be solved.

LUCIAN J. FRONZONI, M.D.

MISCELLANEOUS

The Coexistence of Intra-Abdominal Lesions in Patients with Epigastric Hernia JOHN M. HOFFMAN and GREGG D. WOOD. *Surgery*, 1949, 25, 566.

In a tabulated review of 76 patients admitted to the Portland (Oregon) Veterans' Hospital, the

authors found 24 cases of associated epigastric hernia and upper abdominal disease

The symptoms of epigastric hernia are characterized as (1) a sharp finger-point lancinating pain on straining, well localized to the hernial ring where filaments of the lower intercostal nerves are impinged, and (2) the deep, boring, aching pain aggravated by eating or bending backward, produced by a drag on the greater omentum, greater curvature of the stomach, or falciform ligament of the liver. Pain is relieved on reduction of the mass, or on lying down, and is aggravated by straining, bending backward, or eating a full meal. Thirty of the 76 patients entered the hospital with these symptoms.

Patients with added vague ulcer or digestive symptoms should be thoroughly investigated and even given a trial medical regimen, to rule out coexisting visceral disease, before simple hernioplasty is done. Careful preoperative roentgenograms of the stomach for evidence of gastritis or ulcer, of the gall bladder for disease, and of the colon for disease or malposition, are considered essential, inasmuch as these diseases were predominantly coexistent.

JANE C. MACMILLAN, M.D.

Abdominal Lymphadenitis, Study of 40 Observations (La lymphadénite abdominale, d'après l'étude de 40 observations) JOEL MEGNIN *Rev chir*, Par, 1949, 68 12

The affection which, in the United States, is known as mesenteric lymphadenitis is a syndrome rather than a pathogenetic entity. It occurs most frequently in the second decade of life.

The author differentiates three clinical forms: acute, subacute, and chronic. The pathologic anatomy is not very characteristic except for an enormous swelling of the mesenteric lymph nodes, especially in the ileocecal area. The lymph nodes, which normally are the size of a hemp seed, are increased to lentil or bean size, they are smooth, gray, or pink, and of a special translucent aspect. Although the ileocecal location predominates, enlarged lymph nodes are often found disseminated over the entire abdominal cavity. Histologically they present diffuse hyperplasia, especially of the reticular and endothelial elements.

The etiology of the condition is still an open question, and various writers differ considerably in their opinions. In 1921, Brenneman, in America, suggested that the affection accompanies or follows tonsillitis or other streptococcal infections of the throat. Streptococci were found in a vast majority of cases on throat culture. The author doubts this

theory of the "Brenneman syndrome." Probably a multitude of factors may lead to mesenteric lymphadenitis. Systemic infections such as influenza, pneumonia, measles, scarlet fever, and even poliomyelitis and osteomyelitis are mentioned by the author. On the other hand, intestinal disturbances such as parasites, appendicitis (acute and chronic), and terminal ileitis may play a causative role.

The author discusses 40 personal cases. Of these, 21 patients were operated upon. He includes in his statistics cases of acute purulent appendicitis on the one hand, and abdominal tuberculosis on the other (Abstractor's note. This is surprising, since these conditions should be separated from the syndrome of mesenteric lymphadenitis as it is understood in the United States). WERNER M. SOLMITZ, M.D.

Subphrenic Abscess R. S. HUNT *Brit J Surg*, 1948, 36 185

The present report is based upon 12 cases of subphrenic abscess. Each case is described separately and the anatomy of the subphrenic spaces is briefly discussed.

One patient was found to have a single abscess on the left side secondary to a perforated peptic ulcer, another had abscesses on both left and right sides, secondary to a carbuncle of the left kidney. In all other cases abscesses were on the right, most of them being right posterior, and in general the etiologic factors were either appendicitis or perforated ulcer. However, in 3 cases the condition was secondary to amebic dysentery and in 1 case the abscess was of unknown etiology.

The following conclusions were drawn:

The recognition and early treatment of any predisposing condition, such as appendicitis or peptic ulcer, is of prophylactic value. The predisposing causes must be treated "thoroughly" in order to obtain the best results and prevent relapses. Early drainage is indicated as soon as the diagnosis is made. Diagnostic aspiration or "needling" should be avoided in order to prevent spread of infection or damage to other intra-abdominal organs. The extra-peritoneal approach should always be employed. Extreme caution should be observed in order to avoid the splenic flexure in rare left-sided cases. Because of the varied organisms found on culture, both penicillin and sulfonamides should be used. Finally, the infection seldom corresponds to the anatomical boundaries of a subphrenic space, as it sometimes occupies part of a space and frequently is present in more than one location.

SAMUEL J. FOGELSON, M.D.

GYNECOLOGY

UTERUS

Visualization and Photography of the Uterine Canal W B NORMENT *North Carolina M J*, 1948, 9 619

As a result of many years of attempting to visualize and study the uterine canal, an instrument was devised which consists essentially of a metallic sheath similar to a urethroscope and containing a metal obturator. After the sheath is inserted through the cervix into the uterine canal, the obturator is removed. A second metallic sheath containing the optical system and closed at the end with a transparent window is then inserted through the first sheath. The two sheaths that cover the optical system are air tight and the insertion of the second closed sheath carries a column of air into the uterine canal which causes a slight dilatation which is advantageous for study. This investigation may be done under pentothal sodium or a low spinal anesthetic. It is thus possible to inspect the inside of the uterus and, for the purpose of further study, photographs may also be taken by a camera attached to the optical system. This instrument is an aid in intrauterine diagnosis and is especially valuable for guidance to the exact site where diagnostic curettage should be made. SAMUEL J FOGELSON, M D

Clinical Signs of Adenocarcinoma of the Cervix Uteri (Zur Klinik des Adenokarzinoms der Cervix uteri) H. DRESCHER *Geburtsh & Frauenh*, 1949, 9 31

Seventy-nine patients with adenocarcinoma of the cervix were treated by the author. In suitable cases an operation, namely, an abdominal or vaginal total hysterectomy, or Wertheim's operation, was done and supplemented by preoperative and postoperative x-ray treatments. In 50 per cent of the operable cases a cure was obtained. In the remaining cases fractional x-ray treatment was combined with applications of radium.

Forty-three patients, or 54.4 per cent of the entire group, were operable and a 5 year cure was obtained in 24 per cent of the entire material.

Cylindrical cell carcinoma is less radiosensitive than flat cell cancer, contrary to the flat cell carcinoma of the cervix and the adenocarcinoma of the corpus uteri. The adenocarcinoma of the cervix spreads to the parametria in its early stages. While the squamous cell cancer advances in a wide front, the adenocarcinoma forms clusters of cells separated by normal tissue. This type of advance is much faster than that of the squamous cell cancer.

Unlike cancer of the body of the uterus, cancer of the cervix occurs much more frequently in multiparas than in nulliparas. However, in the author's material the number of nulliparas was twice as large as would be expected.

The author concludes from his study that the results of irradiation in adenocarcinoma of the cervix, with or without operation, are nearly as good as those in cancer of the cervix in general.

JOSEPH K. NARAT, M D

Fibromyxochondrosarcoma of the Cervix Uteri (Fibromyxochondrosarcoma del cuello uterino) JOSÉ M. CUBO and JOSÉ L. BOVERI *Obst gín lat amer*, 1948, 6 554

The authors present an exhaustive case study of a rare uterine tumor. The patient, a 24 year old tripara, had been operated upon for a benign cervical polyp 1½ years previous to her present admission. Metrorrhagia recurred and 10 months later she submitted to a cervical amputation. After a period of 6 months there was recurrence of vaginal bleeding, and on examination at this time a fungating mass which bled freely on the least manipulation was seen attached to the left cervical wall. Microsections revealed a mixed sarcoma. Considerable speculation with regard to the histogenesis of the tumor brought out several theories regarding the formation of these tumors. The possible sequence appears to be as follows:

Because of constant association of the tissues which constituted the tumors, the existence of this link is regarded as sequential and not accidental. The formation of a precartilaginous blastema and the production of a benign cervical chondroma is conceivable. Malignant sarcomatous alteration of this chondroma and its mesenchyma matrix is the next step, with regression of the cartilaginous components due to local factors. The disembryoplastic origin of the tumor suggests the existence of aberrant embryonal germinants since the neoplasm did not show any characteristics of the region involved.

STEPHEN A. ZIEMAN, M D

The Role of Surgery in the Treatment of Carcinoma of the Cervix CHARLES D. READ *Edinburgh M J*, 1948, 55 675

In any discussion on the subject of the treatment of carcinoma of the cervix, division of opinion invariably centers around the relative merits of radiation and radical surgery. This generally applies only to cases coming within the category of stages 2 and 3. In many clinics the Wertheim operation was abandoned when radiotherapy became generally established, but at the author's hospital the radical surgical operation has been practiced continuously, but lately in rather carefully selected cases only.

In his "all out" surgical attack on carcinoma of the cervix, Victor Bonney, between the years 1907 and 1936, performed 500 consecutive Wertheim operations. His operability rate was 63 per cent of all cases seen and his series included stage 1, 2, and 3 growths. His operative mortality was 14 per cent.

In these 500 operations, there was malignant involvement of the regional glands in 200 patients, while in 300 patients the glands were free of growth. The 5 year cure rate in the gland-free cases was 53 per cent, and the corresponding cure rate in the gland-involved cases was 22 per cent. A further analysis of Bonney's results, taking into consideration the 37 per cent of patients not subjected to surgery, shows an absolute cure rate of 25 per cent.

The results of radiotherapy are quoted and compare more than favorably with those of surgery, but in spite of either method of treatment, a considerable number of patients die from the disease.

Since 1936 at the Chelsea Hospital for Women, 14 per cent of the patients with carcinoma of the cervix have been subjected to the Wertheim operation. The operative mortality was 8.3 per cent. With a more careful selection of cases, it is fair to assume that the operative mortality would have dropped to about 4 or 5 per cent as a result of the improved anesthesia, blood and plasma transfusions, penicillin, the sulfa drugs, and good nursing.

The selection of cases for the radical operation today is largely confined to those presenting the following: (1) radioresistant growths, (2) columnar-celled (adeno) carcinoma of the cervix, (3) stenosis of the vaginal vault, (4) large fibroids, ovarian tumor, or salpingitis, (5) refusal of radiation by the patient, and (6) pregnancy complicating cervical cancer.

During the years from 1936 to 1941, 54 radical operations were performed on stage 1 and 2 growths. The uncorrected 5 year survival rate was 44 per cent, the corrected rate was 50 per cent.

The author has performed the radical operation following radiotherapy on 42 occasions. Previous radiation does magnify the technical difficulties of the operation to some extent, but provided the growth still conforms to Stage 1 or 2, it is always removable.

So far as can be assessed, the rate of carcinomatous gland involvement is approximately as follows:

Stage 1	from 20 to 25 per cent
Stage 2	from 30 to 35 per cent
Stage 3	from 40 to 50 per cent
Stage 4	over 60 per cent

The author suggests that radiation may not successfully sterilize the pelvic lymphatic field of carcinomatous deposits, as is illustrated by histological examination of excised nodes following a full course of treatment by radium and deep x-ray therapy. He believes that there is a place for lymphadenectomy in selected Stage 3 cases which have been cured locally by radium, and that such a procedure could well be extended to Stage 2 cases and selected cases of Stage 1.

As for the operation, lymphadenectomy is performed early in the operation immediately after it is ascertained that the bladder can be satisfactorily displaced downward. At least the upper half and preferably the upper two thirds of the vagina are

removed. The ureters and bladder are treated with the greatest gentleness. Over the past 12 years the incidence of postoperative urinary fistula has been 3.1 per cent. GEORGE BLINICK, M.D.

Discussion of Certain Findings at Autopsies of Patients with Cancer of the Uterus (Considerazioni su alcuni reperti di autopsie di pazienti affette da cancro dell'utero) F. MARCHESI *Quad. clin. ostet. ginec.*, 1948, 3: 675

Among 11,693 autopsies there were 82 cases of cancer of the uterus, but 24 of these had to be excluded from the review because the autopsies were incomplete.

In 53 cases of the remaining 58 the cancer was primary and in 5 it was secondary. In 37 cases the cervix was the primary site of the cancer and in 16 the fundus was the primary site.

The author attempted to establish the cause of death in each instance. He divided the causative factors into three groups: (1) direct, namely neoplastic invasion of the lesser pelvis, peritoneal carcinosis, or metastases in the liver or brain, (2) indirect, such as cachexia or renal insufficiency, and (3) intercurrent, such as infectious peritonitis or decompensation of the heart.

Cancer of the cervix caused the formation of fistulas and the infiltration of adjoining organs more frequently than cancer of the fundus.

The frequency of brown atrophy of the liver was greater and that of fatty degeneration of the liver less in cases of cervical cancer than in cases of cancer of the fundus.

Atrophy of the spleen was recorded in 32.4 per cent of the cases of cervical cancer, while septate tumefaction of the same organ was found in 31.2 per cent of the cases of cancer of the fundus.

In 29.1 per cent of the cases of cervical cancer there was hydronephrosis with atrophy of the renal parenchyma, in 24.3 per cent, fatty degeneration, and in 32 per cent, dilatation of the ureters. On the other hand, the frequency of renal lesions in cases of cancer of the fundus was of no practical importance.

The vesical wall was invaded in 24.3 per cent of the cervical cancers and in 6.2 per cent of cancers of the fundus.

The author concludes from his review that the greatest effort should be made to avoid secondary infections and to maintain the anatomic and functional integrity of the urinary apparatus, especially in cases of cervical cancer.

JOSEPH K. NARAT, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Surgical Indication of Hysterectomy with Castration in Hydatidiform Mole (Indication chirurgicale de l'hystérectomie avec castration dans la mole hydatiforme proliférante) CH. FLAMAND *Acta chir. belg.*, 1948, No. 8: 483

The author reports a case of hydatidiform mole with very rapid development and a poor general con-

dition of the patient At 3 months of pregnancy the uterine fundus was at the level of the umbilicus, continuous small hemorrhages had been present for 4 weeks, the patient complained of continuous dull abdominal pains, the hemoglobin was 55 per cent, and the gonadotropic hormone in the urine was 40,000 units According to Aschheim and Zondek the last finding is a classical sign of hydatidiform mole, the titer in normal pregnancy being between 500 and 4,500 units In view of the rapid growth, the extreme softness of the uterus, the probability of incomplete evacuation by curettage, and the poor general condition of the patient, the author decided on hysterectomy As, at laparotomy, the ovaries appeared enormously enlarged (of more than fist size), hyperemic, and polycystic, they were removed with the uterus

The author discusses in detail the indications for hysterectomy in hydatidiform mole He believes that the operation is indicated only in such extreme cases as the one reported In the individual case the decision will depend not only on the rapidity of uterine growth and the general condition but also on the parity of the patient

In the light of recent researches, not too much value can be ascribed to the gonadotropic titer It has been shown that abnormally high titers sometimes also occur in normal pregnancies as well as in hyperemesis gravidarum WERNER M. SOLMITZ, M.D.

MISCELLANEOUS

Irradiation of Spleen (Die Milzbestrahlung) RICHARD KURT KEPP *Geburish & Frauenh.*, 1949, 9: 24

The mechanism of the effect of irradiation of the spleen remains obscure Probably products of decomposition of cells under the influence of x-rays are responsible for the rise of coagulability of the blood

In many instances, irradiation of the spleen not only causes cessation of the uterine bleeding, but also re-establishes the normal cycle This effect is possibly attributable to hormonal relations between the spleen and the ovaries The author irradiates from a distance of 40 cm, with the use of 110 roentgens, 180 to 200 kilovolts, and a copper filter 0.5 c thick

At the University of Goettingen, irradiation of the spleen in the treatment of juvenile menorrhagias, functional hemorrhages of women, preclimacteric uterine bleeding, and hemorrhages due to inflammatory processes of the adnexa, or essential thrombopenia, has been followed by good results

A cessation of juvenile bleeding was recorded in two-thirds of all cases, and in one-half of them a normal menstrual cycle was re-established Seventy-five per cent of all patients with uterine bleeding caused by an inflammation of the adnexa reacted favorably

If the proper technique is employed, the method is considered harmless JOSEPH K. NARAT, M.D.

Clinical Study of 1 Methyl Bisdehydrodoisynolic Acid A New Synthetic Estrogen (Etude clinique de l'acide 1 methyl bisdehydrodoisynolique Un nouvel oestrogene de synthese) ALBERT NETTER, MICHEL JAMES, and G. MATHÉ *C. rend. Soc. fr. gyn.*, 1948, 18: 272

This compound, 1 methyl bisdehydrodoisynolic acid, of strong estrogenic activity, has been prepared by Miescher who gave it this name in honor of the American author, Doisy The formula is

The authors studied this new drug in a series of 33 patients, 18 of whom were in the menopause, 12 had had castrations, and 3 had amenorrhea The substance is given by mouth only Doses of from 20 to 30 mgm re-establish normal vaginal cytology in castrated women In 2 cases of ovariectomized but not hysterectomized patients, doses of from 20 to 30 mgm produced uterine hemorrhage Pruritus vulvae was relieved in 2 women in the menopause The clinical effect on hot flashes, headaches, palpitations, and angiospasm of the extremities was much less marked than that of estradiol

OBSTETRICS

LABOR AND ITS COMPLICATIONS

Medical Treatment of Uterine Inertia (Sul trattamento medico dell'inerzia uterina) ROBERTO PICCOLI *Arch oslet gín*, 1948, 53 276

The efficacy of the association of estrogen with the posterior lobe hormone, and that of sparteine sulfate alone or associated with spasmolytic substances have been studied in 53 cases of uterine inertia. Of 19 patients with simple inertia and early rupture of the membranes, 16 were treated by the oral administration of 4 mgm of diethylstilbene and the intramuscular injection of 3 units of extract of the posterior lobe 4 hours later, in the other 3 patients, 3 mgm of the synthetic estrogen were injected intramuscularly. Before the institution of treatment in all of the cases, the complete absence of uterine contractions was constantly verified by palpation for at least 2 hours. In 13 patients the pregnancy was at term, in 3 it was in the seventh month, and in 3 it was in the eighth month. The presentation was podalic in 2 cases and normal in the others.

In 11 patients uterine contractions started about 3 hours after the administration of estrogen, and in the others within 30 minutes of the administration of the posterior lobe hormone. In 16 patients labor proceeded regularly and spontaneous delivery occurred without complications in an average of 11 hours and 10 minutes. In 2 patients the estrogen treatment started the contractions, but they were of little use and came at rather long intervals even after administration of the posterior lobe hormone. Delivery was obtained after 22 hours by the application of forceps in the first case and in the second case it occurred spontaneously after 33 hours. In the remaining patient, a multipara in the seventh month of pregnancy with ruptured membranes for more than 24 hours and a podalic presentation, the treatment was ineffective in that it caused only weak contractions for 3 hours, and delivery was obtained only after a foot was brought down and traction applied.

Of 34 patients with secondary inertia of the dilatation and expulsion period, 22 were given sparteine sulfate alone in doses ranging from 9 to 20 cgm, while 12 were given 20 cgm of the drug with 3 cgm of paverine.

In the first group, sparteine failed in 2 patients and was effective in the others (90.9 per cent). In from 10 to 20 minutes it caused good contractions which resulted in spontaneous delivery in 65 per cent of the patients, and in more advantageous conditions for operative delivery in the remainder. The contractions caused by sparteine usually last from 30 to 40 seconds and occur at intervals of 3 to 5 minutes. The best results are obtained with doses over 15 cgm. The duration of the action of the drug varies from 2 to 4 hours, but it is seldom necessary to repeat the dose.

In the second group, which consisted of primiparas with simple inertia in whom the borders of the incompletely dilated cervix appeared to be rigid, or in whom the uterus was hypertonic or strongly applied to the fetal body, sparteine associated with papaverine caused spontaneous delivery within a short time in 7 instances and facilitated operative delivery under favorable conditions in 3, but it failed in 2 instances. The association of spasmolytic substances with sparteine does not interfere in any way with the oxytocic action of the latter.

RICHARD KEMEL, M D

Dystocia in Face Presentation (Distocia en la presentación de cara) DIEGO TAYLOR GOROSTIAGA and ROBERTO E LEDE *Prensa méd argent*, 1949, 36 143

The authors, in an elaborate article generously illustrated, discuss the various possible positions of fetal face presentation and the necessity for precise diagnosis of the condition. Every aid should be utilized for this purpose and the criteria for accurate diagnosis are given.

The management of this condition is presented. This includes expectant therapy or manipulation when some disproportion exists. The details of reduction and orientation are enumerated.

The causes for face presentation are given as two-fold and listed as primary and secondary, whereas factors which limit expectant therapy and contribute to the high fetal mortality (from 12 to 50 per cent) involve the maternal organs, their pathophysiologic processes (dystocias), and malformation of the fetus. Considerable judgment and experience are required to decide upon the precise time for surgical intervention as well as to choose the type of surgery suited for the particular case at hand. This is usually determined by the presentation, whether high or low, and the relationship of the maternal and fetal parts.

The various manipulation schemes are discussed, they include rotation, the use of forceps, internal version, symphysiotomy, and cranioclasia.

STEPHEN A. ZIEMAN, M D

Dystocia Due to Obstructing Tumors (Distocia por tumores previos) A WOLFF NETTO *An Fac med*, S Paulo, 1948, 2 23

Obstructing tumors may be genital (uterine malformations, ovarian, uterine, vaginal, and vulvar neoplasms) or extragenital (originating in organs close to the uterus, such as the pelvis, rectum, bladder). They make the normal course of parturition impossible by preventing dilatation of the cervix, or engagement and progression of the fetus through the pelvic canal, or by producing abnormal fetal positions and presentations. Sometimes the dystocia is only apparent and during the course of labor the tumors spontaneously leave their obstructing position and present no further impediments to parturi-

tion When this does not occur, the obstructing tumor requires the intervention of the obstetrician

Tumors obstructing the pelvis are not exceptional complications of labor. Neoplasms of the uterus, and, especially, myomas of the cervix and the lower segment in aging primiparas and in pluriparas with few births or long intervals between them, are the most frequent. In decreasing order of frequency the tumors are ovarian neoplasms (dermoid, pseudomucinous and serous cysts, carcinoma, and sarcoma) and tumors originating in the tissues and walls of the pelvis. Obstructing tumors of the vagina and vulva or those constituted by a pelvic ectopic kidney, fecalomas, vesical calculus, and malignancy of the rectum and bladder are extremely rare. The diagnosis is not always easy and is based on the origin of the tumor, its aspect, consistency, localization, fixation, or mobility. Parturition by the natural route may occur because of the softness or small volume of the tumor, its ascension, or its artificial or spontaneous rupture. If the pelvic obstruction is such as to prevent birth by the natural route and this fact is not recognized, the patient ends by dying from infection or uterine rupture. The treatment of this dystocia must be surgical, it depends on the nature of the tumor but has cesarean section as its basis, which procedure can nowadays be considered rather safe. When it is impossible to displace the tumor manually and to obtain descent of the fetus, this operation becomes imperative and, with or without extirpation of the tumor, solves the problem with decreased maternal and fetal mortality.

The author classifies and discusses the genital and extragenital obstructing tumors, and emphasizes the role played by uterine myomas and cystic tumors of the ovary. He reports 2 cases. In the first, the dystocia was due to a uterine myoma which at first was thought to be a low insertion of the placenta, although there was no hemorrhage. After careful examination the diagnosis of obstructing submucosal myoma was made and it was realized that the localization of the tumor made its extirpation easy. The cervical dilatation was completed and the myoma was removed by torsion of its pedicle. The membranes were then artificially ruptured and the fetal head became engaged. Birth occurred normally 3 hours later. In the second case the dystocia was due to a vulvar tumor and the entire perineal region was occupied by a giant papilloma which obliterated the vaginal orifice nearly completely and made examination impossible. Segmental cesarean section was performed and the tumor was removed by thermocautery 3 months later. RICHARD KEMEL M D

Cesarean Section in Contaminated Cases—A Résumé of 1,138 Observations (La cesárea en el caso impuro [A través de 1,138 observaciones]) JULIO BAZÁN, FRANCISCO A. URANGA IMAZ, and CARLOS D. SCHIAVO. *Bol Soc obst gin B Air*, 1948, 1948 571

This is a critical comparative study of the treatment of cesarean section in contaminated cases with-

out and with chemotherapy and antibiotics. It extends from 1928 to 1948. With the low section technique and drains, the mortality from peritonitis and infection for 172 cases was 4.06 per cent (from 1928 to 1933). Surprisingly, this figure remained about the same up to 1943. Despite variations in operative procedures and care. In 1943 when sulfonamides were employed the rate dropped to half (2.13 per cent). Significantly enough, with improved bacteriologic studies, correct identification of the invading organism, and the employment of specific sulfa-antibiotic combinations, the mortality rate from 1945 to 1948 was reduced to zero in 195 contaminated cases.

Emphasis is placed on culturing of the organism, the skillful operative technique without trauma, and the maintenance of high sulfa-antibiotic concentrations of the blood by local and parenteral means.

STEPHEN A. ZIEMAN, M D

Obstetrical Uterine Rupture in Finland During the Years 1936 to 1943, Especially from the Point of View of Preventive and Clinical Treatment (Ueber die obstetrischen Uterusrupturen in Finnland während der Jahre 1936-1943, insbesondere vom Gesichtspunkt der Präventiven und Klinischen Behandlung aus betrachtet) P. O. PÄRNÄNEN. *Acta obst gyn scand*, 1949, 28 Supp 6

The author analyzes all cases of obstetric uterine rupture occurring in Finland during the years 1936 to 1943. He reports a total of 103 ruptures among 593,251 deliveries (0.17%). The maternal mortality was 53.4 per cent and the fetal mortality, 93.3 per cent. The ratio of multiparas to primiparas was 96 to 13.

So-called violent or traumatic rupture accounted for 17 cases (16.5 per cent of the total). The majority of these followed forceps application and version. In a few cases rupture occurred following craniotomy and embryotomy.

Spontaneous ruptures (86 cases, or 83.5%) were divided as follows: (1) those caused by rupture of a scar (45.4%), (2) mechanical obstruction to delivery (38.4%), (3) pathologic changes of the uterine wall, e.g., neoplasm (9.3%), (4) miscellaneous factors, e.g., pendulous abdomen (2.3%), and (5) undetermined factors (4.6%).

Ruptures of a uterine scar presented the best maternal prognosis (25%). The most usual mechanical obstruction was a narrow pelvis. Two of the 33 cases in this latter group were precipitated by the administration of oxytocics.

The symptoms varied. Classical symptoms of an imminent uterine rupture were frequently absent. At times signs of internal hemorrhage suddenly appeared. It was a common feature for ruptures of scars to be preceded by pain in the region of the scar, perhaps even several weeks beforehand. Nearly 80 per cent of all ruptures occurred within 1 week of term, and four-fifths of these should have been considered early in pregnancy as definite hospital deliveries.

The prognosis seemed to depend primarily on the degree of shock, the severity of hemorrhage, the presence of infection and duration of the rupture before treatment was instituted. Of secondary importance was the general condition of the patient, mode of transportation of the patient to the hospital, and the skill of clinical care.

The author proposes certain principles of management after instituting therapy for hemorrhage and/or shock, definite treatment should preferably consist of wound toilet, and then, if circumstances permit, suture of the rupture, otherwise supravaginal hysterectomy rather than complete hysterectomy should be done. Packing is ill-advised. In patients with persistent hemorrhage the uterine cavity should be emptied either vaginally or by the abdominal route. An empty, retracting uterus is the best security for the control of hemorrhage. It is significant that the mortality among women attended by general practitioners was 77.3 per cent, among those under the supervision of specialists the mortality was only 24.3 per cent.

WARREN R. LANG, M.D.

MISCELLANEOUS

Roentgenologic Study of the Pelvic Viscera in the Pregnant Woman (Etude radiologique des visceres pelviens chez la gestante) M. FOURNIER. *C. rend. Soc. fr. gyn.*, 1948, 18, 202.

Five normal pregnant women, at or approaching term, were studied roentgenologically. Three of these were primiparas and 2 had had a childbirth previously. A sixth woman who clinically presented symptoms suggesting placenta praevia in the sixth month of gestation was later, on Cesarean section, found to have a placenta praevia centralis.

The technique consisted in partially filling the bladder with a shadow medium (tenebryl B). A small barium enema was given by rectum and the vagina was rendered visible by mere intunction of the walls and plications with a thin layer of opaque substance. The roentgen rays were centered between the greater trochanters so that the two shadow contours coincided for the exposures in profiles, and from the middle of the symphysis to the middle of the promontory.

From the experience in these 6 cases it is concluded that cystography will often show a much greater thickening of the inferior uterine segment than vaginal examination with the fingers would lead one to suspect. Although the exact location of the placenta cannot always be found, even when it occupies the lower uterine segment, without a careful study of the relationships also offered by the rectum and the uterus, nevertheless the method is peculiarly susceptible for confirming the clinical diagnosis of placenta previa. On the other hand, in the absence of the signs of abnormal distance between the bladder and the presenting part, and between the rectum and the presenting part, a clinical diagnosis of placenta previa can be discounted.

The author reasons that the method might also apply to other forms of forelying obstructions of the birth canal, such as tumors, fibromas, or cysts.

The roentgenographs show the close relationship between the upper end of the vagina to the rectum in the normal woman at term and explains the frequent injuries to the rectum in vaginal tears. They also show how closely the bladder is molded over the foregoing part contained within the lower uterine segment and the ease of injury to the bladder in tears of this segment.

JOHN W. BRENNAN, M.D.

Abortions, Premature Births, and Weight of the Newly Born During the War Period (Aborti, parti prematuri e peso dei neonati in periodo di guerra) PIERO MUTTI. *Ann. ostet. ginec.*, 1948, 20, 750.

The contradictory reports of various authors who had studied the subject of newborn infants in the two world wars led Mutti to make his own investigation, using the material observed at the Obstetric and Gynecologic Clinic of the University of Cagliari during three periods—the prewar period from 1939 to 1940, the war period from 1941 to 1944, and the postwar period from 1945 to 1946.

He found that the average incidence of abortions had remained nearly uniform, in the neighborhood of 19 per cent, during the three periods. However, the slight increase in premature births to 16.5 per cent during the war period, as compared to 15.6 per cent during the postwar period, was lower than the 17.35 per cent average of the prewar period, and especially the 20.08 per cent of 1939 which constituted the highest point of the curve.

On the basis of 2,614 clinical records referring without doubt to births at term, the average weights of the newborn were 3,291 gm. for the prewar period, 3,316 gm. for the war period, and 3,308 gm. for the postwar period. Consequently, instead of the expected decrease in weight during the war period, there was a very slight increase. Various factors may have contributed to this stability of the weight of the newborn in Sardinia. The war period on this island was shorter than in Northern Italy where the problem has been studied particularly. The island is principally an agricultural region and it is probable that the dietary deficiencies which are capable of profoundly altering the general condition of the mother did not occur here as they did in the other parts of Italy. Pluriparity, in which the weight of the newborn tends to increase with each successive pregnancy, reached its highest point on the island during the war. As a result of the transfer to the island of numerous families of soldiers, many children considered as islanders were really of continental origin, and their average weight at birth was generally higher than that of children belonging to the region. With the influx of continental elements and the intermarriage with island girls, there must also have been some influence on the average weight of the newborn in the direction of an increase.

Mutti also found an increase in the average weight of the newly born offspring of women who were in

tion When this does not occur, the obstructing tumor requires the intervention of the obstetrician.

Tumors obstructing the pelvis are not exceptional complications of labor. Neoplasms of the uterus, and, especially, myomas of the cervix and the lower segment in aging primiparas and in pluriparas with few births or long intervals between them, are the most frequent. In decreasing order of frequency the tumors are ovarian neoplasms (dermoid, pseudomucinous and serous cysts, carcinoma, and sarcoma) and tumors originating in the tissues and walls of the pelvis. Obstetrical Uterine Rupture in Finland During the Years 1936 to 1943, Especially from the Point of View of Preventive and Clinical Treatment (Ueber die obstetrischen Uterusrupturen in Finnland während der Jahre 1936-1943, insbesondere vom Gesichtspunkt der Präventiven und Klinischen Behandlung aus betrachtet) P. O. PÄRÄNEN. *Acta obst. gyn. scand.*, 1949, 28: Supp. 6.

The author analyzes all cases of obstetric uterine rupture occurring in Finland during the years 1936 to 1943. He reports a total of 103 ruptures among 593,251 deliveries (0.17%). The maternal mortality was 53.4 per cent and the fetal mortality, 93.3 per cent. The ratio of multiparas to primiparas was 96 to 13.

So-called violent or traumatic rupture accounted for 17 cases (16.5 per cent of the total). The majority of these followed forceps application and version. In a few cases rupture occurred following craniotomy and embryotomy.

Spontaneous ruptures (86 cases, or 83.5%) were divided as follows: (1) those caused by rupture of a scar (45.4%), (2) mechanical obstruction to delivery (38.4%), (3) pathologic changes of the uterine wall, e.g., neoplasm (9.3%), (4) miscellaneous factors, e.g., pendulous abdomen (2.3%), and (5) undetermined factors (4.6%).

Ruptures of a uterine scar presented the best maternal prognosis (25%). The most usual mechanical obstruction was a narrow pelvis. Two of the 33 cases in this latter group were precipitated by the administration of oxytocics.

The symptoms varied. Classical symptoms of an imminent uterine rupture were frequently absent. At times signs of internal hemorrhage suddenly appeared. It was a common feature for ruptures of scars to be preceded by pain in the region of the scar, perhaps even several weeks beforehand. Nearly 80 per cent of all ruptures occurred within 1 week of term, and four-fifths of these should have been considered early in pregnancy as definite hospital deliveries.

The prognosis seemed to depend primarily on the degree of shock, the severity of hemorrhage, the presence of infection and duration of the rupture before treatment was instituted. Of secondary importance was the general condition of the patient, mode of transportation of the patient to the hospital, and the skill of clinical care.

The author proposes certain principles of management after instituting therapy for hemorrhage and/or shock, definite treatment should preferably consist of wound toilet, and then, if circumstances permit, suture of the rupture, otherwise supravaginal hysterectomy rather than complete hysterectomy should be done. Packing is ill-advised. In patients with persistent hemorrhage the uterine cavity should be emptied either vaginally or by the abdominal route. An empty, retracting uterus is the best security for the control of hemorrhage. It is significant that the mortality among women attended by general practitioners was 77.3 per cent, among those under the supervision of specialists the mortality was only 24.3 per cent.

MISCELLANEOUS

Roentgenologic Study of the Pelvic Viscera in the Pregnant Woman (Etude radiologique des visceres pelviens chez la gestante) M. FOURNIER. *C rend Soc fr gyn*, 1948, 18: 202

Five normal pregnant women, at or approaching term, were studied roentgenologically. Three of these were primiparas and 2 had had a childbirth previously. A sixth woman who clinically presented symptoms suggesting placenta praevia in the sixth month of gestation was later, on Cesarean section, found to have a placenta praevia centralis.

The technique consisted in partially filling the bladder with a shadow medium (tenebryl B). A small barium enema was given by rectum and the vagina was rendered visible by mere innunction of the walls and plications with a thin layer of opaque substance. The roentgen rays were centered between the greater trochanters so that the two shadow contours coincided for the exposures in profiles, and from the middle of the symphysis to the middle of the promontory.

From the experience in these 6 cases it is concluded that cystography will often show a much greater thickening of the inferior uterine segment than vaginal examination with the fingers would lead one to suspect. Although the exact location of the placenta cannot always be found, even when it occupies the lower uterine segment, without a careful study of the relationships also offered by the rectum and the uterus, nevertheless the method is peculiarly susceptible for confirming the clinical diagnosis of placenta praevia. On the other hand, in the absence of the signs of abnormal distance between the bladder and the presenting part, and between the rectum and the presenting part, a clinical diagnosis of placenta praevia can be discounted.

The author reasons that the method might also apply to other forms of forelying obstructions of the birth canal, such as tumors, fibromas, or cysts.

The roentgenographs show the close relationship between the upper end of the vagina to the rectum in the normal woman at term and explains the frequent injuries to the rectum in vaginal tears. They also show how closely the bladder is molded over the foregoing part contained within the lower uterine segment and the ease of injury to the bladder in tears of this segment.

JOHN W. BRENNAN, M.D.

Abortions, Premature Births, and Weight of the Newly Born During the War Period (Aborti, parti prematuri e peso dei neonati in periodo di guerra) PIERO MUTTI. *Ann ostet gyn*, 1948, 20: 750

The contradictory reports of various authors who had studied the subject of newborn infants in the two world wars led Mutti to make his own investigation, using the material observed at the Obstetric and Gynecologic Clinic of the University of Cagliari during three periods—the prewar period from 1939 to 1940, the war period from 1941 to 1944, and the postwar period from 1945 to 1946.

He found that the average incidence of abortions had remained nearly uniform, in the neighborhood of 19 per cent, during the three periods. However, the slight increase in premature births to 16.5 per cent during the war period, as compared to 15.6 per cent during the postwar period, was lower than the 17.35 per cent average of the prewar period, and especially the 20.08 per cent of 1939 which constituted the highest point of the curve.

On the basis of 2,614 clinical records referring without doubt to births at term, the average weights of the newborn were 3,291 gm for the prewar period, 3,316 gm for the war period, and 3,308 gm for the postwar period. Consequently, instead of the expected decrease in weight during the war period, there was a very slight increase. Various factors may have contributed to this stability of the weight of the newborn in Sardinia. The war period on this island was shorter than in Northern Italy where the problem has been studied particularly. The island is principally an agricultural region and it is probable that the dietary deficiencies which are capable of profoundly altering the general condition of the mother did not occur here as they did in the other parts of Italy. Pluriparity, in which the weight of the newborn tends to increase with each successive pregnancy, reached its highest point on the island during the war. As a result of the transfer to the island of numerous families of soldiers, many children considered as islanders were really of continental origin, and their average weight at birth was generally higher than that of children belonging to the region. With the influx of continental elements and the intermarriage with island girls, there must also have been some influence on the average weight of the newborn in the direction of an increase.

Mutti also found an increase in the average weight of the newly born offspring of women who were in

tients with arterial disease, 100 per cent of those with surgical hypertension, and 73 per cent of those with vascular sclerosis

It was not possible to decide from the material studied what produced the hyperfunction of the suprarenal gland in the cases of permanent arterial hypertension, nor was it possible to determine what caused the disappearance of the glomerulosa, and the hypertrophy of the spongiosocyte layer with pigmentary changes in the reticular layer and medulla. This study suggested to the authors the advisability of suprarenalectomy for the treatment of certain hypertensive patients and of certain vascular syndromes

In résumé, the authors studied the histological lesions found in 32 cases in which the suprarenal glands were surgically removed for permanent arterial hypertension. In this group of cases they noted the disappearance of the glomerular zone, hyperplasia of the spongiosa and an increase in the number of islets of lymphocytes. They concluded that these histopathological changes had distinctive characteristics not found in any other disease entity

CONRAD A. KUEHN, M.D.

Instrumental Visualization of the Renal Pelvis

HARRY R. TRATTNER, *J. Urol.*, Balt., 1948, 60, 817

Renal exploration for lesions which cannot be accurately identified by pyelography leaves much to be desired. If the lesion is not apparent in the exposed cortex of the kidney, intrarenal exploration by means of various types of incisions often fails to reveal a "hidden lesion," causes considerable renal damage, and presents problems in hemostasis.

To overcome this shortcoming in renal examination, the author presented a "nephroscope" (a modified cystoscope) by means of which the interior of the renal pelvis and calices may be visualized when the kidney is exposed surgically. The nephroscope is composed of a 24 F straight sheath equipped with 3 telescopes, namely, right angle, fore-oblique, and forward. Grasping forceps can be used with any of the telescopes. A "renal pelvis valve adaptor" is devised to be secured in the incision by a purse-string suture, through this adaptor the sheath of the instrument can be introduced. This device is for the purpose of reducing trauma to the renal pelvis.

The author calls attention to the fact that the kidney must be well exposed (by means of rib resection when necessary), and that the renal pedicle must be of sufficient length and elasticity to allow sufficient mobilization of the kidney for examination. Various types of renal pelvis and calices were discussed from the standpoint of the facility with which examination might be carried out by means of the nephroscope. The author presented drawings to illustrate the various appearances of infundibula, minor calices and pyramids. It is possible by use of this instrument to visualize epithelial tumors, stones, and other pathologic conditions which might otherwise be missed. It is obviously impossible, however, to

visualize all of the ramifications of the calices, except in a minority of cases.

Among the contraindications for the use of this instrument which the author mentioned are (1) conditions which do not permit sufficient mobilization of the kidney with safety, (2) inaccessibility of the renal pelvis because of its type or pathologic involvement, (3) conditions in which it is thought that introduction, injection, or aspiration of fluid into and from the renal pelvis is likely to result in extension or dissemination of an infective process, as in the majority of acute inflammatory conditions and in known cases of renal tuberculosis.

JOHN L. EMMETT, M.D.

Perirenal Abscess OLA OBRANT *Acta chir. scand.*, 1949, 97, 338

In order to establish the results of incision and drainage of perirenal abscesses, investigate the sequelae of the disease, and consider possible alterations in treatment, the author undertook a study of 32 cases of perirenal abscesses in patients previously operated upon during the period between 1920 and 1945. The 32 cases were divided into two groups. The first group comprised 18 cases in which perirenal abscess was secondary to staphylococcal infection of the kidney parenchyma (pyonephritis), and the second group comprised 14 cases in which the etiology was pyelonephritis (infection in the renal pelvis and parenchyma).

In evaluating the statistical data, it was noted that abscesses occurred somewhat more frequently on the right side than on the left. Etiologically, staphylococci were the only organisms isolated in the first group, while various strains were found in the second group. The abscesses were located most commonly inferior to the kidney. None were reported medial to the kidney.

Pain in the renal area, lumbar region, and abdomen was common, however, pain in the legs, joints, and buttocks occurred also in some patients. Anterior abscesses often simulate appendicitis and cholecystitis. Urinary symptoms occurred in 1 patient in Group 1, and in 3 patients in Group 2, with pyuria in the latter group but only bacteria in the former. Leucocytosis was variable, with normal counts occasionally encountered. Fever and an elevated sedimentation rate were rather constant findings. Palpable resistance in the loin was a frequent important finding, but only occasionally was it associated with fluctuation in either group. Roentgenological examination is of paramount importance in the diagnosis. Roentgenograms frequently showed obliteration of the psoas shadow, kidney shadow, a visible mass in the loin, fixation of the kidney on respiration, and calculi, which occurred in 6 cases.

Treatment consisted primarily of incision and drainage. Only 2 patients received chemotherapeutic agents, while none received antibiotics. Of the original number of 32 patients, 18 are living and adequate follow-up examinations were made on 16. The renal shadow on the diseased side was visible in all but 2 patients. In 6 patients in Group 1, relative

GENITOURINARY SURGERY

fixation of the earlier diseased kidney was noted, in Group 2, only one patient revealed this finding, and in 6 cases the findings were relatively normal. Blood pressure findings were inconsequential.

Of the 18 patients in the first group, 14 are living and well, death of 2 patients was due to disease unrelated to the perirenal abscess. In Group 2, only 4 patients are living, and 2 of these have fistulas. Six patients in Group 2 died as a direct result of perirenal abscess and 4 died as a result of the operation.

The author states that generally it is not satisfactory to treat perirenal abscesses (pyelonephritis) by incision and drainage. In nearly all cases there has been some serious disease in the kidney or urinary system, such as concretions, pyonephrosis, infected hydronephrosis, etc. Treatment must be directed against the associated disease as well as the perirenal abscess.

Treatment of Papillary Tumors of Ureter VINCENT J O'CONNOR *J Urol*, Balt., 1949, 61: 488

The author believes that the prognosis in papillary tumors of the renal pelvis and ureter has been spectacularly improved by earlier diagnosis and application of complete nephroureterectomy. This contrasts with the prognosis for cortical renal tumors in which modern surgery has made little progress toward the prolongation of life.

There is at present a lack of definite knowledge as to the etiology of papillary carcinoma of the renal pelvis and ureter, aside from the fact that these lesions are often associated with the presence of stones and chronic infection. There is a generally accepted idea that there must be some irritant to the urinary epithelium by a carcinogenic agent of local origin or one which has been carried to this epithelium by the blood or lymph. Fagerstrom considers epithelial crypts and buds to be bizarre expressions of epithelial hyperplasia and he does not support the theory of cell rests as proposed by Von Brunn. He was unable to develop any evidence that solid epithelial buds are directly associated with the origin of solid tumors of the urinary epithelium.

The author deems it unwise to regard any tumor of the renal pelvis or ureter as being anything but potentially malignant. Incomplete measures such as local excision or destruction are not to be condoned except in unusual circumstances, such as absence or inadequacy of the other kidney. The treatment of choice in dealing with these primary tumors is complete nephroureterectomy with removal of a cuff of the bladder. Incomplete ureterectomy is often followed by recurrence or subsequent tumor development in the ureteral stump, the intramural portion of the ureter, or in the bladder mucosa. These secondary tumors are usually more extensive and less amenable to destruction than the primary tumor.

In support of these conclusions a series of 482 nephrectomies was reviewed. Seventy operations were done for renal or ureteral tumor. There were

14 (2 squamous, 12 papillary) primary renal tumors with secondary implants in the ureter and bladder. Complete procedures were done in 9. In 6 of these the patients are alive for periods ranging from 4 to 22 years. Two cases with incomplete nephrectomy were followed to ultimate death within 8 years and the other within 12 years. Several other cases in which an incomplete nephrectomy was done, including a case in which intramural portion of the ureter was treated by electrocoagulation from without, are listed as showing metastasis in the bladder and pelvis. Of 6 patients operated on elsewhere for papillary tumors of the renal pelvis, 4 died of the primary disease. There were 2 patients seen after being subjected to incomplete operations for tumors of the ureter, both of whom had recurrences in the stump of the ureter with small papillary tumors of the bladder.

Carcinoma of the Ureter JOHN HERMAN LONG *J Urol*, Balt., 1949, 61: 23

A case of primary carcinoma of the ureter is discussed, and a brief review of the literature is submitted, as well as an analysis of pertinent data relative to this entity. Primary ureteral neoplasm occurs either as an epidermoid or as a papillary carcinoma. The condition is observed twice as frequently in males as in females, and occurs in the sixth and seventh decades of life. The lesion occurs twice as often in the right ureter as in the left, and in the lower two-thirds of the ureter twice as frequently as in the upper two-thirds. Hematuria, pain, and an enlarged kidney occur secondary to obstruction by the tumor, ureteral tumor is palpable abdominally, rectally, or vaginally, and lymph nodes may be enlarged. Cystoscopic and roentgenological examinations aid in the diagnosis. The treatment of choice is extraperitoneal nephroureterectomy with segmental resection of the bladder. Metastases are said to occur in 34 per cent of the reported cases, with spread to the retroperitoneal lymph nodes, liver, bones, and lungs. A mortality of 25 per cent is recorded, but no patient living more than 4 years after operation died of metastases. The author recommends periodic follow-up examinations at 3 month intervals during the first year, at 6 month intervals during the second, third, and fourth years, and yearly thereafter.

Transureteropyelostomy and Transureteroureterostomy THOMAS D MOORE *J Urol*, Balt., 1948, 60: 859

In selected cases in which pathologic conditions affect the lower part of only one ureter, it may be desirable to preserve the kidney rather than to perform nephrectomy. Among the conservative operations which have been employed toward this end are reimplantation of the ureter into the bladder, implantation into the bowel, and anastomosis to the normal ureter of the opposite side.

The author reports 1 case of anastomosis of one ureter into the ureter on the opposite side, and 1 case of transureteropelvic anastomosis (anastomosis of a ureter to the pelvis of the opposite kidney) which to his knowledge is the first to be reported in the medical literature. The latter case was that of a woman 30 years of age, who had bilateral ectopic (pelvic) kidneys and backward flow of urine up the left ureter, this caused periodic pain, infection, chills, and fever. The left ureter was isolated, severed from the bladder, brought down through a tunnel under the posterior parietal peritoneum, and implanted into the right renal pelvis, with successful results.

Among the indications for these two types of operative procedure, the author lists unilateral ureteral reflux, surgical ureteral trauma, sloughing of the ureter subsequent to its extensive mobilization and interference with the blood supply, pathologic conditions, either neoplastic or inflammatory, which extensively involved the lower ureter, primary ureteral tumors, either benign or of low grade malignancy, and intractable ureteral strictures.

An account of the author's preliminary operations on animals to determine the feasibility of transplanting a ureter to the opposite renal pelvis is presented. The author calls attention to the fact that, as yet, the successful implantation of a ureter to the opposite renal pelvis of a normally situated kidney in a human being has not been reported. Such a procedure has been performed on cadavers and he is confident that it can be done successfully.

JOHN L. EMMETT, M D

BLADDER, URETHRA, AND PENIS

Cystectomy in the Male. The Significance of the Combined Prostatoseminal Vesiculocystectomy with Special Reference to the Sexual Function. RAGNAR ROMANUS. *Acta chir scand*, 1949, 97 389

The author comments on the various reports which have been made in the literature concerning the operation of cystectomy. He has found (with but one exception) that publications say nothing concerning the sexual function in men after cystectomy.

The author's material consists of 49 cystectomies performed on male patients during the years 1940 through 1947. This operation was performed on 8 patients with extensive papillomatosis of the bladder, 3 patients with severe chronic cystitis with contracted bladder, and 38 patients with vesical cancer and malignant papilloma. Among these 49 patients the prostate was extirpated in 29 cases, and in 28 of these the seminal vesicles were also removed. In 4 of the 20 other cases the prostate was cut approximately in the middle, while in 16 cases it was left largely intact, in 5 of the 16 it was left untouched, and in the remaining 11 cases the division was made through the upper part of the prostate, or the first part of the urethra was cauterized.

During the first years of the period covered by this report, the prostate and the seminal vesicles

were routinely left intact in cystectomy. They were removed only if pronounced adhesions were found with fixation of the bladder to the vesicles, and an extravesical extension was suspected. As a rule, the prostate was removed in cases of tumor in the neck of the bladder with extension to the prostate, and in cases in which changes giving rise to the suspicion of malignancy were observed in the prostate before or during the operation. Of late years, the indications for removal have not been so strictly limited and often are taken out chiefly for technical reasons.

An analysis of the radicality of the operations performed revealed that one argument for removal of the prostate and vesicles was the finding in 6 cases of cancer of the prostate, some of which were unsuspected.

A number of complications have occurred in more or less definite relation to the type of operation performed. There is a tendency for the clamp to slip, owing to division through the prostate instead of distal to the apex.

On 2 occasions fistulas or cavities have arisen which were possibly connected with necrosis of remaining prostatic tissue.

It was the author's impression that urethral drainage was of value in the prevention of retropubic cavities. Epididymitis was found in 3 cases. In 1 instance rectal injury was occasioned when dividing the membranous part of the urethra with diathermy.

Data concerning the sexual function before and after extirpation of the bladder was obtained from 21 patients, comprising 10 in whom the prostate and the seminal vesicles were left, 4 in whom the seminal vesicles were left while the prostate was partially removed, and 7 in whom the prostate and the seminal vesicles were completely removed. In the 10 who had intact prostate and seminal vesicles, 7 enjoyed unchanged sexual function after the operation. There was, however, a temporary impairment in at least 2 cases. In the remaining 3 patients the function has been impaired in 2, in direct relation to the operation and in one secondarily through a subsequently occurring prostatovesiculitis about 5 years postoperatively. In 4 patients the prostate was partially removed, the vesicles being left intact, 2 of these had unchanged sexual functions after the operation but the amount of semen was small.

The last group comprises 7 patients in whom both the seminal vesicles and the prostate were removed. Two of these had unchanged or only slightly impaired sexual function after the operation (apart from the fact that there has been no ejaculation), 1 patient had at first a normal erection but soon died of another disease, 3 patients had inhibited functions after the operation which, in at least 2 cases, may be ascribed to the primary disease and its complications without direct relation to the type of surgery, 1 patient had for a period following the operation a normal libido but was impotent, presumably a consequence of the operation.

In view of these findings the author believes that the disturbances of sexual function which have been

described in connection with operations on the prostate and seminal vesicles must not be ascribed solely to the removal of these organs. Similar changes appear after abdominoperineal extirpation of the rectum and after operations upon the sympathetic nervous systems. These disturbances should therefore more probably be ascribed to nerve injuries sustained in connection with the operation than to the loss of the organs themselves. In an uncomplicated abdominal cystectomy, with removal of the prostate and the seminal vesicles, the dissection of the organs is chiefly made bluntly in the prevesical space and its continuation. Thus, the main nerve plexuses are left undamaged.

On the basis of the present material it is not possible to judge whether the risk of sexual disturbance after cystectomy is greater in connection with removal of the prostate and the vesicles than it is if these organs are left intact. The material is not extensive enough, and it has been selected on the principle that chiefly the most severe cases have been subjected to prostatovesiculectomy and, as a whole, those subjected to this procedure have had a comparatively poor general condition and impaired renal function.

The author's experiences with these 21 patients show that despite the removal of both the prostate and the seminal vesicles, the sexual potential may be normal, i.e., the erection normal, the course of the coitus normal, ending in a normal orgasm but of course without ejaculation. As secondary complications may arise from apparently normal seminal vesicles and prostate left behind at operation, these organs should, on principle, be removed in all cases of malignant vesical tumor, and only in cases of clearly benign changes in patients for whom it is particularly desirable to retain fertility should the preservation of the prostate and the seminal vesicles be considered.

ROBERT O. BEADLES, M.D.

Artificial Urinary Bladder SEYMOUR W. RUBIN *J. Urol.*, Balt., 1948, 60: 874

In this article (awarded first prize by the Committee on Scientific Research of the American Urological Association), the author stated that the important problem to be solved in cases of total cystectomy is not the removal of the bladder, but rather the successful disposition of the ureters. A complete review of the literature concerning uretero-intestinal anastomosis and experimental attempts to form an artificial urinary bladder is given. A complete bibliography is appended.

Because of the frequency of ascending renal infection and ureteral obstruction after transplantation of ureters to the bowel, the author has sought another method for disposing of the ureters when cystectomy is necessary. He presented a review of his work on dogs, in the formation of an artificial bladder from an isolated portion of the sigmoid colon. The operative technique is presented in detail. Briefly, it consists of isolating a 6 to 10 cm. loop of sigmoid and re-establishing the continuity of the

bowel by end-to-end anastomosis. The isolated loop of sigmoid, with its intact musculature, is displaced to the right and its proximal end is closed with sutures. The ureters next are severed from the bladder and anastomosed to the sigmoid loop over ureteral catheters. The bladder is then removed, and the distal end of the isolated loop is anastomosed to the proximal end of the severed urethra.

The operation was successfully performed in 7 of 11 dogs. The dogs were continent, and habits of micturition were almost normal.

The important observation was that postoperative studies did not reveal evidence of pyelocaliectasis or ascending renal infection. The length of postoperative observation varied from a few weeks to 7½ months. At the time of the report there had been some infection in the artificial bladder, but it had been easily controlled with urinary antiseptics. The author stated that there is no reason why this procedure should not be tried on human beings.

Barge-Bourgain's Reaction in Genitourinary Tuberculosis O. SIEVERS and TH. BERGLIN *Acta chir. scand.*, 1949, 97: 283

In 1946 Pirot, Barge, and Bourgain reported on the results of a reaction previously found by Barge and Bourgain with sera from patients suffering from tuberculosis. This reaction is produced by the injection of fresh active patient serum around the lymphatic glands of guinea pigs infected with tuberculosis. Barge and Bourgain consider the formation of a rash in the lymphatic region 8 to 12 hours after the injection to be a positive reaction. The intensity of the reaction is indicated as from 1 to 4 plus.

The original investigators contend that the reaction is positive in patients suffering from tuberculous infections, and they believe the reaction to be of direct diagnostic significance in tuberculous epididymitis, adenitis, and abscesses.

As an explanation of the reaction, Barge and Bourgain assume the escape of various products or toxins from the tuberculous process into the blood stream. They assert that the reaction these products are capable of bringing about in guinea pigs is not identical with the tuberculin reaction, inasmuch as the Barge-Bourgain reaction may sometimes be positive and may at other times be negative in one and the same patient, depending upon the stage of the tuberculous process. If the process is in the healing stage or so encapsulated as to inhibit the escape of such products into the blood stream, the reaction would be negative, or if the tuberculous process is giving off the products in question which are then liable to enter the circulatory system, a positive reaction would be expected. If the reaction is positive, the authors consider the disease to be in a labile stage and they believe that a tuberculous patient ought not to be operated on as long as the Barge-Bourgain reaction is 2 plus or stronger. This con-

clusion is made concerning, above all, genitourinary tuberculosis

The authors examined the sera of 19 different patients with pulmonary tuberculosis, all of whom had been hospitalized on the preceding day on account of deterioration in their tuberculous condition. Sera from 9 of these patients gave a Barge-Bourgain reaction of 3 plus, 4 others gave a plus reaction, 3 were negative, and in 3 cases the control-examined animal exhibited local reddening, for which reason the reaction could not be evaluated. The negative cases were patients with recently diagnosed tuberculosis with short histories.

The authors carried out a number of experiments to try to determine the specificity of the reaction, and his examinations show that it is possible, with the use of material containing the decomposed substances of tuberculosis bacteria, to obtain a reaction similar to that shown by Barge and Bourgain in guinea pigs infected with tuberculosis and injected with serum from tuberculous patients. In these experiments the authors used substrates on which tuberculosis cultures had been grown and tuberculosis cultures which had been carefully pounded. Living tuberculosis cultures suspended in physiological salt solution will not produce such a reaction in the animal. No evidence was produced to show that it was the same substance that appears in the serum of some patients when the guinea pig tests are positive, in Barge and Bourgain's conception of the term. It could, however, be stated that the reactions in both cases exhibit similar pictures and that it is not incredible that the two substances are identical. If such is the case, this must be accepted as a sign that Barge and Bourgain's reaction really is a specific reaction.

CLINICAL EXPERIENCE WITH BARGE-BOURGAIN'S REACTION

Berglin examined material consisting of 111 cases, among which there were 17 cases of nontuberculous disease of the urogenital system and 25 cases of other nontuberculous diseases, the remainder were tuberculous.

Of 60 patients with clearly diagnosed tuberculous diseases, a negative test was observed in 23 cases, or 38 per cent. Of the 41 patients who primarily reacted positively, 34 were clearly tuberculous from the beginning or were later found to be so. Six cases, 5 of which were epididymitis and 1 aseptic pyuria, had been strongly suspected of tuberculosis clinically. In only 1 of the 41 cases with a positive Barge-Bourgain reaction was tuberculosis really doubtful. This case was one of the very first, and had been recorded as weakly positive, so it is possible that the reaction may not have been positive. The Barge-Bourgain reaction in all of the 17 controls, consisting of nontuberculous cases of urinary tract infection, were negative. Likewise, the 23 judgeable

controls consisting of nonurogenital cases were clearly negative.

On the basis of these findings the author considers that the examinations argue for Barge-Bourgain's contention that the reaction is specific from a diagnostic point of view. It must be pointed out, however, that only a positive reaction is of diagnostic value.

The reaction was of special value in the early diagnosis of obscure cases of tuberculosis of the urinary tract. In a number of cases of renal tuberculosis the reaction was immediately suggestive of a specific diagnosis which could not be confirmed by the bacterial examination until much later.

The possible value of the test in determination of the developmental phase and possible activity of tuberculous infection was indicated in the study when 14 of 15 cases of primary (positive) urogenital disease showed signs of activity or revealed activity in the later course of the disease.

The 13 cases of pulmonary tuberculosis with positive reaction were all in a clinically active stage. The 2 cases located elsewhere were both in an active stage. Thus, of 30 primarily positive cases there was but one case that did not show any signs of activity. These findings warrant the following conclusions.

If the Barge-Bourgain reaction is positive, a tuberculous process in the active state is strongly indicated.

The value of the reaction as an indicator of the activity of a tuberculous infection was conspicuous in those cases in which a positive Barge-Bourgain reaction was not accompanied by clinical signs of activity, but in which the later course of the disease revealed a distinct activity of the process.

In contradistinction, a negative reaction does not exclude the existence of an active tuberculous process.

As an indicator of the activity, the Barge-Bourgain reaction is expected to be of greatest importance from a surgical point of view. By operating during the most favorable phase of the disease a direct spread of the process may be avoided. In the author's experience, and that of others, the patient should not be operated on as long as the reaction is positive. Follow-up examinations of these cases revealed that the reaction became negative much more rapidly on patients who were hospitalized than on those who had been released with a positive reaction. The authors believe that patients in whom the reaction is positive and in whom the disease is, in all probability, in the active stage, should be considered acutely ill and therefore confined to bed.

The authors' findings corroborate those of previous workers and furnish some valuable clinical information on a reaction which will, in all probability, be of great significance in the diagnosis as well as in the treatment of tuberculosis.

ROBERT O BEADLES M D

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Paralytic Equinovarus Deformities of the Foot J LEONARD GOLDNER and C E IRWIN *South M J*, 1949, 42 83

The authors herein discuss two types of feet, both of which are classed as paralytic equinovarus deformities (1) equinovarus foot with contracted Achilles tendon, cavus, contracted plantar fascia, depressed first metatarsal head, and claw toes, and (2) the rigid recurrent equinovarus foot

Abnormal physiology and etiology are discussed in an orderly and lucid manner. Some of the points made are that muscle imbalance predisposes to fixed deformity. Contracture of the plantar fascia ensues. Relaxed subastragal and midtarsal joints magnify the deformity. Abnormal distribution of body weight increases the varus once it is present.

A standard method of recording the functional strength of muscles is described. This together with analysis of bone age and architecture of the foot is a prerequisite to treatment.

Nonsurgical measures are outlined for children under 9 years of age, who are still in the period when muscle strength is returning or who are too young for surgery. Lengthening of the Achilles tendon may be required occasionally. Tendon transplants alone, without stabilization, are usually not indicated. The importance of the posterior tibial muscle has frequently been overlooked.

Operative treatment of patients more than 9 years of age is designed to (1) stabilize and align the foot, (2) remove deforming factors, (3) eliminate joint pains, calluses, and limp, (4) obviate leg braces, and (5) restore normalcy in appearance.

Surgical procedures for adults include

- 1 Plantar fasciotomy
- 2 Triple arthrodesis (after the method of Hoke, in such a way that the dorsum of the foot is shortened in ratio to the strength of the extensor muscles, the plantar surface is elongated, and the varus of the forefoot and heel is corrected)
- 3 Wedging of the forefoot upward after from 7 to 10 days
- 4 Tendon surgery 4 weeks after stabilization
- 5 Correction of external torsion of the tibia by a high greenstick rotation osteotomy at the same time the tendon work is done

In the case of the rigid recurrent equinovarus, the surgery is as indicated for relapsed clubfoot.

Charts showing combinations and procedures applicable in performing tendon transplants after arthrodesis are submitted in concluding this article. The drawing and the photographs are excellent and further serve to illustrate the well written text.

KENNETH E SHERMAN, M D

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC

Surgical Treatment of Osteoarticular Tuberculosis (Tratamiento quirúrgico de la tuberculosis osteoarticular) ALBERTO INCLÁN, JR. *Cir ortop traumat*, Habana, 1948, 14 75

Forty-three cases of bone or joint tuberculosis treated surgically are reviewed by the author. Among the recent additions to the surgical armamentarium in the treatment of this disease the author mentions the following: the use of the Haynes splint for immobilization of the knee joint following arthrodesis, the use of streptomycin after excision of the diseased tissue in 3 cases of tenosynovitis, and the employment of the Brittan technique for extra-articular arthrodesis of the hip and shoulder.

Articular resection is employed now only in exceptional cases, such as tuberculosis of the elbow in adults, certain lesions of the wrist, and certain types of hip disease.

The introduction of antibiotics which are able to control secondary infections has limited the indications for amputation greatly. As a rule, arthrodesis constitutes the method of choice in the treatment of osteoarticular tuberculosis. The effect of this operation may be compared with that of thoracoplasty in the treatment of pulmonary tuberculosis, i e, it provides immobilization of the involved region.

Extra-articular arthrodesis is preferable to the intra-articular type in the treatment of articular tuberculosis because it avoids entering the articular capsule and reactivating or disseminating the specific infection.

Tuberculous abscesses should be treated by repeated aspiration and not by incision and drainage. Only Pott's abscess, which produces compression of the spinal cord, may require drainage. Another exception is the retropharyngeal abscess which should be drained if it causes dyspnea or dysphagia.

Of 205 cases of osteoarticular tuberculosis, 43 have been treated surgically, among them being 15 cases of Pott's disease and 17 cases of disease of the hip.

JOSEPH K. NARAT, M D

Delayed Autogenous Bone Graft in the Treatment of Congenital Pseudarthrosis JOHN ROYAL MOORE *J Bone Surg*, 1949, 31-A 23

A discussion of the theories of the etiology of congenital pseudarthrosis and of various methods of treatment is presented. The histopathological characteristics of the lesion have been generally accepted as conforming to those of acquired pseudarthrosis. Inert, sclerosed, pointed, atrophic bone ends surrounded by a sleeve of dense connective tissue and developing ultimately the characteristics of a nearthrosis including the cartilage and joint cavity are the principal findings in the mobile type. The author

theorizes that the end product of osteogenesis (laminated bone) in the pseudarthrosis area is defective in quality, in that it is not only incapable of withstanding the physiological stresses, but is equally incapable of repair

He classifies the lesion into two principal types (1) prepseudarthrosis, the stage in which the long bone is bowed or bowing, the apex of the bow is narrow, the medullary cavity becomes obliterated, and spontaneous or induced fracture occurs, followed by pseudarthrosis, and (2) pseudarthrosis, which may be fibrous to frank nearthrosis

With this hypothesis the delayed autogenous bone graft is presented, it is an excellent means of producing osteogenesis. The delayed graft is one which is completely freed of all attachments at the donor site of the tibia, fibula, or ilium. It is replaced in the original site and the wound closed. In from 18 to 21 days it is carefully removed with its new-bone components and implanted in the fragments comprising the pseudarthrosis

Careful attention is paid at operation to removal of the pseudarthrosis and preparation of the bed for the graft. For immobilization during operation in tibial sites the author uses the Abbott bone-lengthening apparatus with four steel wires in the tibia and an intramedullary wire in the fibula. The tibial fragments are split to the nearest wire and the tibial bone graft is wedged in. He also recommends grafting the fibula at the same time. He approaches both bones through the anterior compartment through one incision. The wound is closed in layers. Routine light dressings are covered by a plaster cylinder (including pins) which extends from the toes to the groin. In cases in which lengthening is required, the delayed graft must not be started until the lengthening is completed and the operative wound has healed. For a pseudarthrosis of the ulna, femur, or clavicle, delayed onlay grafts are used with secure internal fixation as well as external immobilization.

The pins and plaster are maintained until the medullary cavity appears in the graft, which requires an average of 4 to 6 months. Then, in the case of the tibia, a double-bar caliper brace, extending from the ankle to the groin, is applied. This brace has a pelvic band and a full length tibial leather cuff. This is worn for 2 years. Roentgenograms are taken bi-monthly during this period.

Successful osteosynthesis has been accomplished in 8 cases of congenital pseudarthrosis. In 6 cases the deformity was in the leg, and in one case each, in the ulna and femur. In 2 cases, three delayed grafts were required, and in 1 case an additional bone graft was required for reinforcement to prevent possible fracture. In 2 cases spontaneous fracture occurred, and traumatic fracture occurred once in each of 3 cases, which necessitated the extra grafting mentioned previously.

Illustrative roentgenographic reproductions accompany the text. Photomicrographs of immediate and delayed bone graft histology, as well as that of pseudarthroses are shown.

The author concludes that the delayed autogenous bone graft is capable of stimulating osteogenesis. The extra supply of alkaline phosphatase and the attached newly formed bone may contribute to osteogenesis. Bony union has occurred in each instance. The principal problem is one of meticulously nurturing the young bone until it can withstand the physiological forces and, later, the functional demand. Reinforcement of the newly formed tibia at its weak point, as evidenced by narrowing or incipient bowing, is imperative. Continuation of primary immobilization until the medullary cavity is formed is emphasized.

KENATH H. SPONSEL, M D

Transfer of a Metacarpal G L HYROOP *Plast Reconstr Surg*, 1949, 4 45

The first transfer of a metacarpal with the attached digit was reported by Bunnell in 1931. This was a transfer of a second metacarpal with partial amputation of the index finger.

The aim in any type of reconstructive surgery is to restore or to improve function, sensation and cosmetic appearance. Loss of the thumb, for example, with the first metacarpal, produces a serious disability of the hand.

Under special circumstances it may be well to repair the skin, nerves, bones, and tendons before the metacarpal is transplanted to determine the sensation and the amount of function that is to be expected in the digit. If a tendon pulley is required the deficiency should be corrected before transfer of the digit is undertaken. Adductor contractures between the thumb and index fingers and other scarring may have to be repaired. Exposed bone and soft tissues must be covered. Surgery may not be performed for from 6 months to a year following the healing of osteomyelitis. When there is amputation of the thumb, or of the long or ring fingers because of tumor, transfer may be carried out immediately or later, in accordance with the type of lesion present.

A brief discussion of operative technique is included. Indications for the operation with reference to the thumb and also the other fingers are given. Illustrative drawings, photographs of roentgenograms of the hands as well as illustrations of the hands are shown. The article is based upon the author's experience with 34 cases. The advantages of metacarpal transfer are that recovery following surgery is quite rapid, and that the nerve and vascular supply are retained. KENNETH SHERMAN, M D

Results of Intertrochanteric Osteotomy in Pseudarthrosis of the Femoral Neck (Risultati di osteotomie intertrocanteriche per pseudoartrosi del collo femorale) G DE LUCCI and A NURRA. *Chir org movim*, 1948, 32 421

The authors report on 42 cases treated by intertrochanteric osteotomy at the Istituto Rizzoli of Bologna, Italy, from January 1, 1940 to December 31, 1945. This was performed for nonunion of fractures of the femoral neck.

A stable hip, with some shortening (not exceeding 4 cm), some limitation of hip motion, with no pain and a perceptible limp is considered a good result.

The authors quote Putti as saying that it is impossible to expect a perfectly functioning articulation following this procedure. They stress that it is important that the thrust force be exerted directly under the head in weight bearing. This frequently results in a solid bony union between the head, the intertrochanteric osteotomy area, and the greater trochanter. In the authors' experience, a not uncommon cause of failure in this procedure has been the inaccurate placing of the femoral shaft under the head.

Immobilization of the osteotomy site for from 5 to 6 months is recommended. A long leg abduction cast is replaced by a short leg abduction cast at the end of 10 or 12 weeks.

In the 42 cases reported the results are evaluated as good (21) fair (7), and bad (8). The remaining 6 cases did not have adequate follow-up.

The Pauwel classification of hip fractures is discussed.

CARLO SCUDERI, M.D.

Arthroplasty of the Knee Joint J. EDOUARD SAMSON *J. Bone Surg.*, 1949, 31-B 50

The author bases his findings on 72 patients who were operated on between 1924 and 1941. In 4 of these patients an arthroplasty was performed in both knees. The femoral and tibial condyles were removed freely. A central ridge was left on the tibial plateau to correspond with the intercondylar notch of the femur. A free fascial flap measuring 15 by 10 cm. was used to cover the bony surfaces.

Early motion was encouraged. The author infiltrated the knee joint with novocain to enable his patients to move the knee freely. Bilateral arthroplasty of the knee was discarded because it was found that the development of a second knee arthritis was usually beyond the capacity of the patient. The lower age limit was set at 20 years. In 52 per cent of the author's patients a stable and painless joint was obtained. Poor results were found in 48 per cent.

GEORGE I. REISS, M.D.

Arthroplasty of the Knee J. S. SPEED and PHILIP C. TROUT *J. Bone Surg.*, 1949, 31-B 53

The residual effects of acute infective arthritis of hematogenous origin, of suppurative arthritis of external origin, and the results of incomplete painful ankylosis or complete ankylosis of the knee joint were found to be the only indication for arthroplasty. Multiple rheumatoid arthritis, tuberculosis, osteomyelitis, obesity and osteoporosis were considered as contraindications for arthroplasty of the knee joint.

The operation consisted of building a simple type of hinge joint. The extensor apparatus was not disturbed. A sufficient amount of bone was removed from the posterior femoral condyles to allow the tibia to slide into the popliteal space. If only one-half of the knee joint was ankylosed no arthroplasty was performed because it failed in all instances. It

was found that fascial covering of the condyle was not necessary but that it helped until fibrocartilage was formed. The cruciate ligaments had to be sacrificed.

The most sufficient range of motion was between 180 and 110 degrees. Motion beyond the 90 degree angle may produce instability. Pain was observed in a few patients. The author stated that in 45 per cent of the cases the results were classified as good and in 20 per cent they were failures.

Watson Jones opposed arthroplasty of the knee because he felt that the patient could not depend upon his knee. He stated that an arthrodesis was not too great a handicap and that arthroplasty was indicated only if there was ankylosis of both knees or of the hip and knee of the same side. Freiberg presented a patient operated on in 1935 who had a very good result. Cleveland pointed out that the author reported only one-third of all the knee joints operated on and discarded two-thirds because of various reasons. Less than 50 per cent of the patients were classified as having a good result. He pointed out that this left a very small number of good results and advocated extreme caution in the selection of cases for arthroplasty.

GEORGE I. REISS, M.D.

On Arthrodesis of the Ankle Joint in Posttraumatic Conditions A. KARLÉN *Acta orthop scand.*, 1948, 18 175

The author reports the results of 24 cases of tibio-tarsal arthrodesis for post-traumatic conditions. Bony ankylosis was obtained in all cases. Twenty-one patients are fully able to work, 2 are doing light work, and 1 is still under treatment (supplementary subastragalar arthrodesis). Three patients have secondary osteoarthritis of the neighboring joints.

These procedures were performed during the period from 1936 to 1946 at the Orthopedic Clinic of the Karolinska Institute in Stockholm. The majority of operations were performed for fractures of both malleoli or for trimalleolar fractures. Exclusive intra-articular arthrodesis has been practiced as the earliest operative procedure. Gradually, insertion of one, and later of two transarticular bone grafts completed the surgical interference.

When all reported cases are considered, the argument that ankylosis of the talocrural joint is difficult to obtain seems to be refuted by the average duration of the ankylosing phase, amounting to 3.1 months. Fusion occurred most readily after intra-articular arthrodesis combined with fixation of two grafts across the articulation.

Immobilization of the ankle joint imposes increased strain, particularly on Chopart's joint. Evidence of this condition is given by an increased range of movement (to 30 degrees) that subsequently appears in that joint. Also the subtalar joints may be considered as being exposed to increased, abnormal strain which is due either to a decreased rate of pronation and supination, or, at least, to a certain elasticity in the ankle joint. Secondary

arthrosis deformans involving the exposed joints may be expected and referable to these increased strains

In order to avoid such discomfort the author advocated a panastragalar arthrodesis and this procedure was carried out in 10 cases. No pain arose from the midfoot postoperatively in 8 of these cases. Hallgrimson has reported on 15 cases of poliomyelitis which were followed up after panastragalar arthrodesis. In 6 of them, there was a more or less increased range of movement in Lisfranc's joint, this movement, however, never exceeded 20 degrees. Two patients complained of subsequent slight pain.

Nevertheless, the author did not think that panastragalar arthrodesis should become a generally used procedure in preference to talocrural fusion because of the greater duration of the operative procedure in the injuries sustained by the soft tissues, necrosis of the skin, etc. Tibiotarsal arthrodesis combined initially with subastragalar (tri-articular) arthrodesis is confined to cases which have already (before operation) developed osteoarthritis in the subastragalar and midtarsal joints.

C. FRED GOERINGER, M.D.

FRACTURES AND DISLOCATIONS

Avascular Necrosis of Large Segmental Fracture Fragments of the Long Bones EDWARD L. COMPERE. *J. Bone Surg.*, 1949, 31-A 47

Five cases are presented in detail in which there was avascular necrosis of large segmental fracture fragments of the long bones. In these cases it may be predicted that there will be a marked delay in union of the large segmental fracture of the midshaft or ends of a major long bone. The larger the fragment, the poorer the prognosis, from the standpoint of viability of that fragment. If most of the cells die in the fragment it will become necrotic, although massive sequestration does not occur. Union may be delayed for many months. With good fixation, healing of the fracture will take place. If the nutrient artery remains uninjured, aseptic necrosis may not occur.

RICHARD J. BENNETT, JR., M.D.

Traumatic Posterior (Retroglenoid) Dislocation of the Humerus JOHN C. WILSON and FRANCIS M. MCKEEVER. *J. Bone Surg.*, 1949, 31-A 160

Posterior dislocation of the humeral head is relatively uncommon, but it is also frequently unrecognized until weeks after its occurrence when treatment is difficult and the prognosis uncertain.

Eleven males, presenting a total of 12 posteriorly dislocated shoulders, were studied. Four dislocations, including the bilateral ones, resulted from epileptic convulsions, and the rest from violent external trauma.

Concomitant fracture of varying degrees occurred in 8 of the shoulders and contributed to failure of early diagnosis of the dislocation in more than half of the cases.

Review of the pathological findings in the patients operated upon shows that the type and extent of damage depends upon the degree of violence producing the original dislocation. Nerve damage is rarely encountered. Clinical recognition of the posterior dislocation is easy before swelling obliterates the landmarks and in old untreated cases. Adequate roentgenograms are imperative, especially lateral views, which can be interpreted without unusual difficulty.

In the first hours after injury, reduction is readily accomplished under anesthesia, but it is not easily maintained. The necessary position of marked internal rotation is most uncomfortable for a period of time. In 3 dislocations, the reduction was safely and comfortably held by fixing the head to the acromion process with cruciate wires. These may be inserted and then removed after 3 weeks without open operation. Only a sling is needed for support, and the early motion that is possible allows good recovery of function.

The results of late treatment are poor because of gross joint changes and fibrosis.

FRANCES E. BRENNKE, M.D.

Indication for Operative Treatment of Fractures of the Proximal Portion of the Upper Arm (Zur Indikation der operativen Behandlung von Frakturen im koerpernahen Abschnitt des Oberarmes) HERMANN KARCHER. *Chirurg*, 1948, 19 553

Conservative treatment of fractures of the proximal portion of the upper arm is advocated by the author because it furnishes good functional results. In dislocation fractures an operative treatment is indicated only if (in exceptional cases) conservative measures fail.

The author is not in favor of operative procedures because:

- 1 There is no danger of pseudarthrosis in this region.
- 2 An open reduction inhibits callus formation, delays consolidation, and frequently irritates the articular capsule.
- 3 The open articular capsule is easily subject to infection and the proximity of the nail to the articulation frequently causes effusions.
- 4 The hospitalization period is not shortened but rather prolonged after an open reduction, furthermore, a readmission is necessary for removal of the nail.
- 5 Periodic examinations show that the results of open reduction are poorer than those of conservative treatment.

An impacted fracture of the surgical neck is immobilized in a sling or by a Desault dressing.

A thoracic abduction cast is applied in case of a nonimpacted fracture, with good apposition of the fragments.

Malposition of the fragments is corrected by closed reduction under local or general anesthesia. If the reduction is unsuccessful, a wire extension is applied.

The same method is employed in the treatment of subcapital fractures and dislocations

JOSEPH K. NARAT, M.D.

Follow-Up Results of Surgical Treatment for Nonunion of the Carpal Scaphoid Bone Report of 19 Cases C. FRED GOERINGER, *Arch Surg*, 1949, 58: 291

Twenty operations were performed on 19 patients with nonunion of the carpal scaphoid. The bone graft was taken from the tibia. One case of nonunion persisted following the bone grafting.

In 8 of the 16 cases supplementary drilling was carried out, and it is believed that the follow-up indicates that this procedure would be of value in selected cases. A large chart is included giving voluminous details about each case. Six roentgenograms are included.

In 2 instances the proximal fragment was removed, and in 1 instance, the distal fragment. These patients are said to have pain and limitation of motion in the wrist postoperatively.

The author suggests that arthrodesis of the wrist is preferable to excision of one or more of the carpal bones.

RICHARD J. BENNETT, JR., M.D.

Management of Intracapsular Hip Fractures ROBERT T. McELVENNY, *Surg Clin N America*, 1949, 29: 31

The author states that an intracapsular fracture of a femoral neck in an elderly patient is no surgical emergency but may well be a medical emergency. The patient is put to bed with boards under the mattress and 5 pounds of Russell traction. Proper padding is placed beneath the buttocks and above the rubber sheet. The patient is encouraged to use the hand attachments of the overhead frame, and to sit up and move about. He is turned from side to side frequently. Small doses of morphine, codeine, and aspirin may be prescribed. A complete medical survey is made, and surgery is postponed until medical balance is obtained, which averages from 7 to 10 days. The patient is typed for transfusion. Postoperatively the patient is again placed in moderate traction and only one hypodermic of $\frac{1}{12}$ grain of morphine is given. Thereafter codeine by hypodermic injection or codeine and aspirin are given orally for pain. Penicillin is given routinely. Deep breathing exercises are given, but the patient is not out of bed for from 10 to 21 days. Meanwhile exercises of the extremities are encouraged. The patient is then placed in a wheel chair, and later is taught to use crutches, but weight-bearing is not permitted until 4 to 6 months postoperatively.

The operative procedure as described by the author takes from 1 to 2 hours. He prefers anesthesia by pentothal induction followed by the inhalation of 50 per cent nitrous oxide and 50 per cent oxygen, sometimes supplemented by small additional injections of pentothal. After anesthesia the patient is placed upon the cassette holder with a narrow perineal post. Traction is applied to both extremities.

The reduction is accomplished and checked with anteroposterior and lateral views. No surgical preparation or draping is done until completely satisfactory reduction is shown by adequate roentgenograms in both planes. Routine exposure and insertion of the guide wire through a quarter inch drill hole is described. Placement and depth are checked with roentgenograms and the length of the cannulated nail is determined. A starter is used and then the nail is driven in. Roentgenograms in both planes check the position of the nail.

The author attempts to differentiate between aseptic necrosis, a rare complication in his series, and delayed union, a common complication. Following 65 hip operations for fracture there were 11 failures (16.78%). The failures consisted of 1 case of aseptic necrosis, 2 cases of nonunion, 2 of non-reduction (immediate osteotomy), 5 of delayed union, and 1 death. There were no serious infections. The excellent results obtained were attributed to the efficient reduction, so that the roentgenograms in both planes showed the neck fragment under and medial to the head fragment in a true valgus position.

DANIEL H. LEVINTHAL, M.D.

Comminuted and Segmental Fractures of the Leg KELLOGG SPEED, *Surg Clin N America*, 1949, 29: 1

Comminuted fracture of the leg, simple or compound, often presents problems not successfully treated by any uniform routine method, however, the purposes of treatment should be carefully noted: (1) restoration of limb length, (2) restoration of the axial relationship of the knee and ankle, (3) maintenance of the integrity of the soft parts by gentle handling and consideration of the nerves and vessels, and (4) maintenance of reduction until adequate callus can hold the fragments.

An injured leg should be splinted and the patient put at rest. The circulatory status of the limb should be noted, as well as muscle function. X-ray study of the limb in anteroposterior and lateral views should be made. With careful handling of the leg the tissue should be prepared with a soap and water scrub, any open wounds being covered with sterile sponge. Hair should be shaved off. Then the preparation is continued with 70 per cent alcohol and a dye antiseptic if desired. The surgeon may elect the closed or open method of treatment, according to the circumstances of the injury, the type of fracture, and his operative experience and training. The fracture dislocation is reduced on the fracture table by fixed or manual traction, and the leg is securely encased in a padded plaster cast from the upper thigh to the toes. The cast may be incompletely bivalved in anticipation of swelling, and the limb is elevated on pillows. In some cases continuous traction is preferred by means of insertion of a Steinmann pin through the calcaneus and suspension of the limb in balanced traction, with the Thomas splint. Distraction is to be avoided by x-ray follow-up. Transfixion pins and outside bars are not a generally accepted method of treatment.

A satisfactory method of treatment is the use of the Steinmann pin through the calcaneus for traction in reduction, then another pin is placed transversely through the tibial tubercle and the whole limb is encased in plaster for about 8 to 12 weeks. It is then removed and followed by a walking boot cast, if healing has been satisfactory and sufficient callus and bone are noted in the roentgenogram. The use of the walking iron stirrup, unless carefully planned, is dangerous.

DANIEL H. LEVINTHAL, M.D.

Treatment of Malleolar Fractures According to Lauge Hansen's Method Preliminary Results
T. BAEK KRISTENSEN *Acta chir scand*, 1949, 97
362

On the basis of 200 cases of ankle fracture treated according to Lauge Hansen's method, the system of classification, manners of production, and mechanisms of reduction are reviewed.

Supination-eversion fractures The supinated foot is everted, i.e., the tip of the foot is turned outward around a vertical axis. The characteristic feature of this type is the oblique spiral fracture involving the lateral malleolus and the adjacent part of the fibula.

Supination-adduction fractures The foot is supinated and adducted at the talocrural joint, thereby causing an avulsion fracture of the lateral malleolus (or lesion of the ligamentum calcaneofibulare). The characteristic feature of this type of fracture is the transverse fracture of the lateral malleolus on a level with, or distal to, the articular surface of the ankle joint.

Pronation-eversion fractures When the foot is pronated, the deltoid ligament is tightened. The characteristic feature of this type of fracture is the high fracture of the fibula.

Pronation-abduction fractures When the foot is maximally pronated, the deltoid ligament is tight-

ened. The characteristic feature of this type of fracture is the bending fracture of the fibula at a point a little above the ankle joint.

Pronation-dorsiflexion fractures By forced dorsiflexion of the pronated foot, pressure is exerted by the talus on the tibia and medial malleolus. The characteristic feature of this type of fracture is the large fracture of the anterior lip of the tibia.

The material reported here comprises all the cases of ankle fracture treated in the Surgical Department from November 1, 1942 to November 1, 1946. The follow-up examination took place at least 12 months after the accident. Among 200 patients, there were 116 men and 84 women, a distribution roughly corresponding to that found in other reports. Cases of epiphyseal separation have not been included.

In 120 of the 200 patients studied, it was necessary to reduce the fractures, 115 were reduced at once. In 106 cases the result was good, in 8 the result was fair, and in 1 case the result was poor. Open reduction, osteosynthesis, and wire extension were not employed. If the control roentgenograms showed good position, a rubber-covered wooden block, serving as a heel, was incorporated 2 or 3 days later, and usually the patients were allowed to get out of bed and were discharged after another couple of days. The time in bed after the application of the plaster cast averaged 42 days for patients with uncomplicated fractures.

In the classification and end results, the author adopted various criteria which seemed to be acceptable. An analysis of the causes of the poor results was made in the various types of fractures. The pronation-abduction fractures have given the greatest percentage of poor results, whereas no poor results were found among the supination abduction fractures subjected to follow-up examination.

C. FRED GOERINGER, M.D.

A satisfactory method of treatment is the use of the Steinmann pin through the calcaneus for traction in reduction, then another pin is placed transversely through the tibial tubercle and the whole limb is encased in plaster for about 8 to 12 weeks. It is then removed and followed by a walking boot cast, if healing has been satisfactory and sufficient callus and bone are noted in the roentgenogram. If the control roentgenograms showed good position, a rubber covered wooden block, serving as a heel, was incorporated 2 or 3 days later, and usually the patients were allowed to get out of bed and were discharged after another couple of days. The time in bed after the application of the plaster cast averaged 4 2 days for patients with uncomplicated fractures.

In the classification and end results, the author adopted various criteria which seemed to be acceptable. An analysis of the causes of the poor results was made in the various types of fractures. The pronation-abduction fractures have given the greatest percentage of poor results, whereas no poor results were found among the supination-abduction fractures subjected to follow-up examination.

C. FRED GOERINGER, M.D.

bility of the blood and a strong tendency to bleed, especially following trauma. It is always present for life. Transmission is always through the female to the second generation, the genes being sex-linked and recessive. The coagulation defect is observed in vitro as a prolongation of the whole blood clotting time from a normal of 6 to 12 minutes to many hours. Most of the patients in the authors' series have clotting times of 1 to 2 hours. It is generally agreed that the fibrinogen, prothrombin, calcium, and the *number* of platelets are all normal.

The authors report the cases of 40 patients aged 12 years or over who have been followed during the last 10 years. All were males. Seventy per cent of these had a family history of hemophilia. There were 5 deaths, 3 were caused by conditions unrelated to hemophilia, and none occurred as the result of acute hemorrhage. Bleeding into joints is the most frequent hemorrhagic episode of adult hemophiliacs. It is recurrent, so that eventually many joints acquire some degree of permanent damage, the knees and elbows being most frequently involved. In only 2 of the series was there no evidence of *chronic* hemophilic arthritis, and the authors state that one would hesitate to make the diagnosis of hemophilia without the presence of joint deformity unless the diagnosis could be otherwise conclusively established. Purpura is not the characteristic finding here that it is in purpura hemorrhagica. Bleeding into muscle almost always follows severe trauma and may spread so dangerously as to result in shock. Attacks of hematuria are one of the most frequent hemorrhagic episodes, almost 90 per cent of this series having suffered one or more such episodes. Hematuria may be painless unless clots are passed. It may last a day or so, or may be prolonged for several weeks, no known factor or form of treatment apparently affecting the duration. Other less common bleeding phenomena are hemophilic pseudo bone tumor, pharyngeal hematomas, pulmonary and

pleural bleeding episodes, and the abdominal and retroperitoneal bleeding episodes which may mimic acute surgical conditions of the abdomen. Intracranial hemorrhage is rare.

Transfusions of whole fresh blood or plasma separated soon after phlebotomy are effective in correcting the coagulation defect, although bleeding may continue in spite of the coagulation time having been brought to normal. Whole blood may be given in amounts necessary to replace that lost or, if blood is not necessary, plasma in amounts of 100 to 250 cc may be given. The correction of the coagulation time may persist for 6 to 12 hours. Thus, for continued bleeding, blood or its derivatives should be given once or twice daily during the period of active bleeding. Blood plasma fractionation has led to the production of Fraction I, a preparation of human fibrinogen which contains antihemophilic properties and which can be conveniently and quickly given. Its limitations are its production in limited amounts and the probable transmission of hepatitis, which occurred in 2 cases in this series.

For local bleeding, thrombin (held in place with some form of pressure dressing) is preferred as a coagulant. Major surgery is hazardous and the estimate of Friedrich of a mortality of 35 per cent is probably conservative. Free use of preoperative and postoperative blood transfusions and thrombin, wherever possible, are the only important additions to a careful surgical technique. A detailed plan of treatment for the many types of bleeding disabilities to which hemophiliacs are heir is presented, with emphasis upon the suitable management of dental extractions and dental hygiene.

The authors conclude with the statement that the physician must not slight the social, economic, and psychiatric implications of the disease in his efforts to aid the patient to learn to live with his disease.

ALLAN D. CALLOW, M.D.

Incompetency of the valves is treated by exposure of the deep veins in Hunter's canal and ligation of the superficial femoral vein. Perivenous cicatrization is treated by removing the fibrous tissue mantle from about the vein. Ulceration is treated by sympathectomy with ligation of the superficial femoral vein and subfascial ligation of the communicating veins.

Recurrent streptococcal infections are avoided by careful hygienic care of the legs and feet. Acute attacks are treated by immediate rest in bed and prompt institution of antibiotic therapy.

Tissue-Culture Evaluation of the Viability of Blood Vessels Stored by Refrigeration E CONVERSE PEIRCE, II, ROBERT E GROSS, ALEXANDER H BILL, JR, and KEITH MERRILL, JR *Ann Surg*, 1949, 129 333

After the authors had studied various methods of preservation they used tissue culture techniques to demonstrate viability of the blood vessels, and concluded that storage of the vessels in the 10 per cent homologous serum and balanced salt solution (Ringer's solution) at temperatures slightly above freezing gave uniformly viable vessels. Of six methods studied, this was the most successful, the frozen vessels showing growth on tissue culture in only 2 of 34 experiments. Small pieces of tissue stored alone gave poor results, but their viability could be maintained by adding a large piece of tissue to the substrate.

The authors report that vessels so stored have been safely used in dogs and humans for homoplastic grafts.

BLOOD, TRANSFUSION

The Rh Blood Groups and Their Clinical Effects P L MOLLISON, A E MOURANT, and R. R. RACE *Med Res Council, Lond*, 1948, No 19

In England the Medical Research Council, realizing that there is an urgent need for an authoritative summary of the present knowledge on the subject of the Rh blood groups and their clinical effects, has prepared a most welcome memorandum on this subject. It seems inevitable that a discovery which is so intellectually satisfying and so practically effective should, of course, gather around it a very bulky literature and one that seems to grow as the research in this field progresses.

First of all the division and classification of the Rh groups are discussed. Second, the clinical considerations and importance of the Rh groups, and, third, Rh testing are discussed.

The discovery of the Rh factor in human blood and the recognition that human beings can be clas-

hemolytic disease of the newborn, and hemolytic reactions that occasionally follow transfusions even when a reliable and blood type was used.

The brilliant discoveries by Levine in 1939 of an atypical immune agglutinin in the blood of a woman after a stillbirth was the first of rapid developments which led up to the concept of the Rh blood groups and their clinical manifestations. In 1940 Landsteiner and Wiener reported finding the Rh antigen. Most of the research investigations were actively carried out by Taylor, Mollison, Race, Wiener, and Fisher.

It soon became apparent that Rh testing should be made a routine before the administration of any type of blood. Even now, however, there is a tendency to ignore the need for such tests and to emphasize the need for such tests and to emphasize the two main dangers avoided by using the Rh test. First, the transfusion of Rh-positive blood to Rh-negative persons has been sensitized by either a pregnancy or a blood transfusion may kill them. Second, the transfusion of Rh-positive blood to an Rh-negative person sensitizes her to the Rh antigen, so that a child subsequently born to her may be diseased or even stillborn. The injection of a small amount of Rh-positive blood may cause life-long sensitization.

In discussing the clinical considerations the authors mention that many tragedies have been averted by routine Rh testing and by not transfusing Rh-positive blood to an Rh-negative person. By this simple measure alone it has been estimated that about 20 or 25 per cent of all cases of hemolytic disease could be prevented, as well as a large number of fatal transfusion reactions. The direct comparison of the donor's and the recipient's blood is a valuable safeguard against fatal transfusions from Rh as well as from the blood group compatibility, but it is no safeguard against the possibility that a transfusion may sensitize and thus lead to a future hemolytic disease. Therefore, in circumstances in which Rh testing cannot be performed, who have not passed the child-bearing period, certainly receive Rh-negative blood if it is obtained.

Rh testing during pregnancy is desirable but has not at present the same importance as testing before transfusion, since no means of sensitization of an Rh-negative mother during pregnancy are known.

The present state of our knowledge of the Rh blood groups and their clinical effects is completely summarized in this excellent memorandum.

EDWARD F LEWIS

The second case was that of a patient who, 10 days after an electric shock, developed attacks of dyspnea, precordial pain, and severe palpitations. Examination of the heart and vascular system were negative, an electrocardiogram was not done. Four infiltrations of the left stellate ganglion resulted in complete cure.

In view of these spectacular successes, the author discusses the advisability of performing infiltration of the regional sympathetic ganglia routinely after all electric injuries in order to prevent secondary vasomotor disturbances.

Wounds of the Extremities. SIR THOMAS FAIRBANK, F. A. R. STAMMERS, R. J. FURLONG, J. M. P. CLARK, and Others. *Brit J Surg*, 1949, War Surg Supp 2.

This summary of the principles of military surgery is based on the experience of surgeons of the British Armed Forces in World War II. In wounds of the extremities, which formed such a large proportion of the total, the results generally were definitely better than those in the First World War. In both wars, the treatment of the wounded in the later campaigns reached a standard which, for various reasons, was impossible in the earlier. The rate at which the number of cases of unhealed wounds has diminished since the end of the war speaks for itself, when we recall that after the First World War thousands of similar cases required repeated admission to the hospital over a period of many years.

Some of the numerous factors which contributed to the improved results were the better organization of the medical services and mobile surgical units prepared to function anywhere, but particularly as close to the front line as circumstances permitted, these units brought operative surgery to the more severely wounded at the earliest possible moment, which fact is rightly regarded as being of paramount importance.

In Britain, the mistakes of the First World War were avoided, much greater care being taken in the selection of suitable hospitals for the reception of convoys, and in ensuring that patients in need of specialized treatment were transferred to suitable units without delay. There were far more specialists available to handle cases of exceptional difficulty. Resuscitation teams were at hand wherever the surgeon went, saving innumerable lives, and in desperate cases transfusion was started as far forward as the Aid Post and continued in the ambulance as it traveled to the surgeon.

The actual surgical treatment was performed along the same lines as in the earlier war in wounds of the extremities but with modifications as a result of further experience, discoveries, and new ancillary treatment. Pains were taken to train the young uninitiated surgeons, for it was soon recognized that the most single important factor in the treatment of all wounds was the skill and efficiency with which the primary surgical treatment was carried out. With regard to muscle damage in particular, the truth of

this is generally accepted. The sulfonamides and antibiotics cannot replace surgery entirely in the treatment of wounds. Modern surgical treatment employs many adjuncts to the operative techniques, that are of great value. Chemotherapy, fluid replacement, transfusion of whole blood and the various fractions of blood employed as substitutes, potent anesthetic agents, and narcotics properly administered are of inestimable value in treating the wounded.

The ever present necessity for evacuation to the rear divided the technical surgical management into first aid measures, initial wound surgery, secondary wound surgery at the base as definitive or reparative, and reconstructive and rehabilitation measures. The phases of surgical treatment as listed above in general with the military echelons, just as the placement of the various types of hospitals and, consequently, the provision of facilities for surgical treatment were determined by the geographic deployment of a military force. The essential feature about organization in the forward areas is that it should be elastic, and from the surgical point of view, the establishment of field surgical units, and field transfusion units, together with casualty clearing stations and new field dressing stations, made this possible. The most important advances affecting the medical services during the Second World War were (a) the well organized service by which blood and other intravenous fluids, including plasma, were readily available in adequate quantities, (b) the development of highly mobile surgical units—the Field Surgical Unit, (c) chemotherapy, particularly penicillin, and (d) better means of communication, since the fate of casualties depends upon them in great measure, to these should be added the Bailey Bridge, the bulldozer, and the jeep.

In forward areas specialist teams were tried but they were not a success since in most instances casualties could not be held long enough postoperatively for adequate observation. It was found best, because of improved and more rapid evacuation and transport, to place specialist teams at the Base or on lines of communication farther back where there were special units for fractured femurs and other complicated fractures, the chest, the head, burns, vascular injuries, and peripheral nerve injuries. The only exceptions to placing specialist teams at Base were the placing of neurosurgical and maxillofacial units along the lines of communication in the Army Area.

The first surgical intervention then, in everything except neurosurgical and maxillofacial lesions, was made by general surgeons in the forward areas, and there was no question of segregation of special types of cases until the Base was reached. These forward surgeons were picked, experienced surgeons, able to tackle anything, and their real task was to eliminate factors that were of immediate danger to life and limb, and to prepare the patient for later reconstructive procedures to be undertaken on the lines of communication or at the Base.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE, POSTOPERATIVE TREATMENT

Blood Supply of Cross Leg Pedicle Flaps R. B. STARR *Plast Reconstr Surg*, 1948, 3 694

The cross leg pedicle flap is an expedient for the transplantation of whole thickness skin and subcutaneous tissue to a defect of the foot or leg. From the point of view of the comfort of the patient, the medial aspect of the calf and the anterior aspect of the thigh offer the best donor sites upon which to construct pedicled flaps. The posterior aspect of the calf and the medial aspect of the thigh also have been used as donor sites for either open or tubed pedicles. The relative vascularization of the soft tissues of the various areas of the lower extremity cannot be determined by reference to standard texts of anatomy.

Several methods were used to gain information concerning the location of macroscopic arteries of the various surface areas, the size of the arteries, and their relative, quantitative vascular beds. Cadavers from the anatomical laboratory were used. After withdrawal of the embalming fluid from the arteries, commercial umbrathor (colloidal thorium dioxide, from 24 to 26%) was injected into the arterial tree through a cannula in the femoral artery. The degree of filling was determined by x-ray examination of the extremity. Once filling had been accomplished, circumferential flaps of whole thickness skin and subcutaneous tissue were cut from the extremity, just above and just below the knee. They were removed completely from the extremity, the line of dissection being accurately placed at the junction of the subcutaneous tissue and the fascia. The upper margin of the circumferential flap of the leg was at the level of the medial condyle of the tibia and the head of the fibula with its vertical incision along the crest of the tibia. The size of the usual pedicled flap allows only three possible donor areas in the leg: the medial, posterior, and lateral. The thigh affords four possible donor areas: the anterior, medial, posterior, and lateral. In an endeavor to determine the relative vascularity of the three available donor sites of the leg, the circumferential band of whole thickness skin and subcutaneous tissue was divided by lead markers into equal medial, posterior, and lateral thirds. The same procedure was used upon the flap from the thigh where four possible donor sites were demarcated equally. Roentgenographs were taken of these circumferential flaps. Inspection of the films showed that the arteries which reach the tissues of the surface were accurately outlined by the opaque medium.

In the second method of study a refrigerated embalmed cadaver was used. The vascular tree of the right lower extremity was washed out with physiological saline solution. Liquid latex rubber

was injected into the arterial tree. After the body had been refrigerated for approximately a month, a circumferential flap was cut below the knee as outlined previously. The flap was subdivided by an incision into three equal donor areas. Each rectangular block of tissue was placed into a separate basin where all of the soft tissues were digested by a solution of sodium hypochlorite, according to Danforth's method. The tissue digestion left the unaffected latex vascular casts. Since the latex filled only the arterial tree, the casts represented molds of the arteries of the skin and subcutaneous tissue. These molds were carefully weighed.

The observations reported herein indicate that the medial aspect of the calf and the anterior aspect of the thigh are donor sites of choice since it has been shown that arteries are most abundant in these areas. The posterior aspect of the calf and the posterior aspect of the thigh show the fewest arteries. It is known that pedicles from the posterior third of the calf may be used with success if cautiously delayed, but this area is not the donor site of choice, and its indiscriminate use may occasionally lead to failure. The lateral third of the calf has an arterial supply second to that of the medial third of the calf but it is usually difficult to base a pedicle upon that surface. The medial aspect of the thigh has somewhat fewer arteries than has the anterior aspect of the thigh but the difference is not great. Clinically this area has been used principally for tubed pedicles with success.

FRANK F. KANTHAK, M.D.

ANTISEPTIC SURGERY, TREATMENT OF WOUNDS AND INFECTIONS

Sequelae of Electrocution and Infiltration of the Stellate Ganglia (Séquelles d'électrocution et infiltration stellaire) PIERRE OURY and RAYMOND DENNIEL. *Presse méd*, 1949, 57 147

The authors report 2 most interesting cases in which the late sequelae of electrocution were cured rapidly by novocain infiltration of the stellate ganglia.

The first patient presented the picture of severe vasomotoric disturbances of both hands 2½ months after an electric shock. The hands up to the wrists were of bright red color, "like lobster claws," extremely edematous, and quite limited in movement. The patient complained of diffuse dull pains and was unable to do any work. Ten infiltrations of the stellate ganglia, four on the right side and six on the left, brought about complete cure.

The author discusses the probable mechanism of this spectacular cure. It is interesting that infiltration of the sympathetic ganglia has a beneficial effect not only on spasms of the blood vessels as in Raynaud's disease but also in extreme dilatation as in the present case.

SURGICAL TECHNIQUE

The second case was that of a patient who, 10 days after an electric shock, developed attacks of dyspnea, precordial pain, and severe palpitations. Examination of the heart and vascular system were negative, an electrocardiogram was not done. Four infiltrations of the left stellate ganglion resulted in complete cure.

In view of these spectacular successes, the author discusses the advisability of performing infiltration of the regional sympathetic ganglia routinely after all electric injuries in order to prevent secondary vasomotor disturbances.

Wounds of the Extremities SIR THOMAS FAIRBANK, F.A.R. STAMMERS, R.J. FURLONG, J.M.P. CLARK, and Others. *Brit J Surg*, 1949, War Surg Supp 2.

This summary of the principles of military surgery is based on the experience of surgeons of the British Armed Forces in World War II. In wounds of the extremities, which formed such a large portion of the total, the results generally were definitely better than those in the First World War. In both wars, the treatment of the wounded in the later campaigns reached a standard which, for various reasons, was impossible in the earlier. The rate at which the number of cases of unhealed wounds has diminished since the end of the war speaks for itself, when we recall that after the First World War thousands of similar cases required repeated admission to the hospital over a period of many years.

Some of the numerous factors which contributed to the improved results were the better organization of the medical services and mobile surgical units prepared to function anywhere, but particularly as close to the front line as circumstances permitted, these units brought operative surgery to the more severely wounded at the earliest possible moment, which fact is rightly regarded as being of paramount importance.

In Britain, the mistakes of the First World War were avoided, much greater care being taken in the selection of suitable hospitals for the reception of convoys, and in ensuring that patients in need of specialized treatment were transferred to suitable units without delay. There were far more specialists available to handle cases of exceptional difficulty. Resuscitation teams were at hand wherever the surgeon went, saving innumerable lives, and in desperate cases transfusion was started as far forward as the Aid Post and continued in the ambulance as it traveled to the surgeon.

The actual surgical treatment was performed along the same lines as in the earlier war in wounds of the extremities but with modifications as a result of further experience, discoveries, and new ancillary treatment. Pains were taken to train the young uninitiated surgeons, for it was soon recognized that the most single important factor in the treatment of all wounds was the skill and efficiency with which the primary surgical treatment was carried out. With regard to muscle damage in particular, the truth of

this is generally accepted. The sulfonamides and antibiotics cannot replace surgery entirely in the treatment of wounds. Modern surgical techniques, employs many adjuncts to the operative techniques, that are of great value. Chemotherapy, fluid replacement, transfusion of whole blood and the various fractions of blood employed as substitutes, potent anesthetic agents, and narcotics properly administered are of inestimable value in treating the wounded.

The ever present necessity for evacuation to the rear divided the technical surgical management into first aid measures, initial wound surgery, secondary wound surgery at the base as definitive or reparative, and reconstructive and rehabilitation measures. The phases of surgical treatment as listed above in general with the military echelons, just as the placement of the various types of facilities for surgical treatment, determined by the geographic deployment of a military force. The essential feature about organization in the forward areas is that it should be elastic, and from the surgical point of view, the establishment of field surgical units, and field transfusion units, together with casualty clearing stations and new field dressing stations, made this possible. The most important advances affecting the medical services during the Second World War were (a) the well organized service by which blood and other intravenous fluids, including plasma, were readily available in adequate quantities, (b) the development of highly mobile surgical units—the Field Surgical Unit, (c) chemotherapy, particularly penicillin, and (d) better means of communication, since the fate of casualties depends upon them in great measure, to these should be added the Bailey Bridge, the bulldozer, and the jeep.

In forward areas specialist teams were tried but they were not a success since in most instances casualties could not be held long enough postoperatively for adequate observation. It was found best, because of improved and more rapid evacuation and transport, to place specialist teams at the Base or on lines of communication farther back where there were special units for fractured femurs and other complicated fractures, the chest, the head, burns, vascular injuries, and peripheral nerve injuries. The only exceptions to placing specialist teams at Base were the placing of neurosurgical and maxillofacial units along the lines of communication in the Army Area.

The first surgical intervention then, in everything except neurosurgical and maxillofacial lesions, was made by general surgeons in the forward areas, and there was no question of segregation of special types of cases until the Base was reached. These forward surgeons were picked, experienced surgeons, able to tackle anything, and their real task was to eliminate factors that were of immediate danger to life and limb, and to prepare the patient for later reconstructive procedures to be undertaken on the lines of communication or at the Base.

The principles involved in the care of wounds of the extremities and the parietes do not differ from those applicable to all wounds. Primary considerations are (1) arrest of hemorrhage and treatment of shock, (2) prevention of additional contamination and trauma, (3) diagnosis of the extent of the injury, (4) conversion of a contaminated wound into a clean wound if the time interval permits, (5) removal of foreign material and devitalized tissue, (6) repair of injured structures, (7) purposeful splinting and dressing to provide rest and an adequate circulation for the injured tissues, whether bone or soft tissues, and (8) clean surgical care until healing is complete.

First aid, resuscitation and transport. Every man carried on him a first aid dressing, and when wounded either he or some comrade applied it to the injured part. If ambulatory, he would make his own way to the regimental aid post or to some other collecting post, otherwise he was rescued by stretcher bearers readily, larger dressings (shell dressings) and splints such as the Thomas splint would be applied for femur injuries. Then he was taken by ambulance to the advanced dressing station where a medical officer made any necessary adjustments to the dressings and to splints, administered antitetanus serum, morphine when necessary, and 2.5 gm of sulfonamide by mouth, which was to be continued throughout the journey. Blood, plasma, and glucose-saline solution were available at Advanced Dressing Station and full resuscitation could be given. For extensive muscle injuries gas gangrene antitoxin was administered. It was a rule that no wound should be exposed unless the patient was in severe pain or showed a rising pulse and temperature.

Loss of blood. It has been demonstrated by hematocrit, blood volume, and clinical studies that in major muscle wounds the loss of blood is usually great. It soon became appreciated that plasma and glucose-saline solution were of value, but that replacement of blood by blood was the best treatment. Excessive transfusion was harmful and in some cases was followed by anuria and uremia.

Dehydration. Most wounded men were in a state of dehydration. Heat in warm regions, sweating, and diminished fluid intake during combat increased the body temperature sometimes to 103 or 104 degrees. After hemorrhage, dehydration, together with the outpouring of serum into bruised tissues, often led to hemoconcentration and accounted for an erythrocyte count of 6,000,000 and the hemoglobin at 112 per cent. Glucose-saline solution given intravenously in adequate amounts (from 5 to 7 or 8 pints daily with sodium chloride not to exceed from 10 to 12 gm daily) corrected dehydration. The daily output of urine should be over 1,000 cc and must be not less than 500 cc.

Infections and other results of injury. Gas gangrene is a specific disease of devitalized muscle and its genesis is the whole environment of war, for the circumstances under which a fighting force lives, works, and is wounded are such as to encourage it. The incidence may be as high as 5 per cent with a

mortality of 50 per cent, but with increasing experience these figures were reduced to about 1 per cent and 20 per cent, respectively, and after penicillin became available the mortality was reduced to about 10 per cent. It cannot be emphasized too strongly that no crushed or lacerated muscle is free from the danger of gas gangrene and all crushed, torn, and devascularized muscle must be excised to eliminate the nidus most favored by the clostridia. The fundamental factor in the disease is damage to the blood supply, and anything that embarrasses the circulation of the limb, such as tourniquets, tight bandaging, badly applied splints, and the trauma of ambulance journeys, encourages it, the more general factors of severe hemorrhage, exposure, starvation, and absorption of toxic products of infection and muscle necrosis render the victim more susceptible. Various color changes are observed in and about the wound, the muscle being plum-colored, salmon-red, greenish-black, or black with a general tendency toward dryness, such discharge as there is being foul-smelling serum which may or may not contain bubbles of gas. Occasionally the diseased muscle is yellow and friable. An outstanding feature is that the involved muscles neither bleed nor contract when cut. The skin is affected late, but as tension increases it becomes pale, and later becomes mottled from hemolysis. With gas-forming organisms it is tympanic. Of great importance is the intense necrosis that results in the liver and kidney cells which accounts for the common terminal symptoms of scanty blood-stained urine or anuria.

The symptoms may declare themselves as early as 5 or 6 hours, but usually appear from 24 to 48 hours, after wounding with sudden onset and rapid advance. The victim becomes pale, livid, anxious, afraid, or euphoric, but is mentally alert. His pulse quickens and becomes feeble, dicrotic, and running, the blood pressure is low, the extremities are cold, blue, and clammy. The temperature varies from some rise to subnormal and is not significant. These facts emphasize the crucial difference between contamination and infection, the most important fact in the established case is the profound toxemia. The picture is one of peripheral vascular failure, and mimics three other conditions, namely, advanced peritonitis, major muscle wounds of 3 or 4 hours' standing, and acute hypoproteinemias. Such patients are utterly prostrated, and unless immediate and vigorous surgical measures are applied death is imminent. Gas, when present, can be demonstrated by roentgenographs. Errors arise by the attempt to diagnose the condition by its odor, many contaminated wounds are by necessity malodorous but in the absence of severe prostration this does not point to gas gangrene. Penetrating wounds may permit the entrance of air into the soft tissues which may give a sensation of surgical emphysema.

Treatment is essentially prophylactic from the moment of wounding. It is assumed that first aid is properly executed—adequate splinting, bandaging that is adequate and not too tight, strict adherence

to the rules regarding the application of tourniquets, correct application of the Thomas splint, keeping the patient warm, relief of pain, administration of antitoxic and gas gangrene antitoxin, control of shock, and transportation to the nearest surgical center with dispatch

The proper surgical treatment of all wounds is a requisite, but for the established case blood transfusion, antitoxin, and penicillin are essentials. All affected muscle must be excised and this may be done best by removing the entire muscle from origin to insertion and remembering that the blood vessels of the muscles run within the bellies longitudinally, which explains why the infection tends to spread longitudinally. Large muscles like the adductor magnus may demand only partial resection, but it may be necessary to sacrifice the entire gluteal group. All discolored muscle and any that does not bleed or contract must be excised. A limb may be so disorganized that amputation is the only solution. A heavy penicillin frosting is applied to the wound and 100,000 units of gas gangrene antitoxin are given intravenously. Penicillin, blood transfusions, fluids, and plasma are administered postoperatively.

Tetanus Every soldier was protected by tetanus toxoid before going abroad and, if wounded, was further treated by antitetanic serum. The experience of the Americans and the French indicates that tetanus toxoid is sufficient. The incidence of tetanus was exceedingly low and, as in the case of sepsis generally and for clostridial infections in particular, adequate surgery with dispatch is the best safeguard against the disease.

Trauma and malaria In malarious areas trauma might precipitate acute clinical malaria even though it were controlled hitherto by suppressive anti-malarial agents. High fever and malaise were indications to examine a blood film. The cerebral type was confusing in the presence of a head wound or in cases of fat metabolism from limb injuries.

Anuria This dysfunction was associated with crushed limbs, major muscle wounds, gas gangrene, abdominal wounds, transfusions of excessive amounts of blood or of incompatible blood, and large doses of sulfonamides, which precipitated acetylated derivatives with blockage of the tubules, ureters, and pelvis, in addition, transfusions, either excessive in quantity or of incompatible blood, lead to choking of the glomeruli and tubules by agglutinated and disintegrated red corpuscles. In extensive burns, severe dehydration and hypoproteinemia lead to hemoconcentration and oliguria and because of delayed treatment may progress to anuria. Since the war, Trueta and his coworkers have proved by experimental crushing of limbs that the main arteries in the lower limbs pass into spasm which ascends the vascular tree until the renal arteries are reached and are similarly affected. It has also been postulated that lacerated muscle was absorbed into the circulation which led to a prolonged fall in the blood pressure, as a result of which irreversible degenerative changes took place in the renal cells from ischemia.

The onset of anuria is heralded when the urine becomes dark and scanty and finally suppressed, the tongue and skin are dry and the blood urea rises to uremic levels (300-400 mgm per cent). Patients developing oliguria may recover or may develop anuria, dying between the sixth and eighth days. Anuria resulting from large doses of sulfonamide is treated by pressing fluids and trying to dislodge the deposits in the ureters by ureteric catheterization. For the remainder, alkalization and fluids form the mainstay of treatment. Since the war, peritoneal dialysis, artificial kidney, and the injection of novocain around the celiac ganglia to abolish renal vessel spasm have been advocated.

Fat embolism and the effect of blast It was not an uncommon experience to find a patient with a limb injury who became drowsy from 24 to 36 hours postoperatively, then lapsed into coma, and died with cerebral manifestations 2 to 4 days later. Papilledema was never present, and retinal hemorrhages were found rarely. Neck rigidity occasionally evolved, reflexes were usually exaggerated, and signs of a pyramidal tract lesion, such as extensor plantar response, sometimes appeared. When lumbar puncture was performed there was no finding grossly. The brain at autopsy showed the same changes in both groups of cases—generalized petechial hemorrhages throughout the white matter. When lung complications were also present, the bubble of air beneath the pleura suggested that the whole condition resulted from blast. It seemed probable that when the cerebral signs were present from the beginning the condition was one of blast, but when they were delayed they resulted from fat embolism. Some of the specimens at the Base showed fat globules in the kidneys, urine, and brain. There was no effective treatment for either.

The surgical treatment of wounds The influence of time, terrain, climate, and type of missile is fundamental. In active, moving warfare in which it is not possible to hold any but the seriously wounded men in the Forward Areas, there is no place for primary suture. This is because the majority of casualties will be subjected to the trauma of long ambulance journeys of unpredictable duration over bad roads, during which time they will not be under constant observation of a surgeon who might detect impending complications.

Infection remains relatively superficial for the first 8 hours after wounding, and is less severe in a dry climate than in a cold, wet one. It is, therefore, easier to render a wound surgically clean if treated within 8 hours of wounding, and units should be deployed accordingly. The heaviest contamination of wounds occurs in cold, wet weather when fighting is in the liquid mud of highly cultivated soil. Such wounds require thorough excision at the earliest possible moment, and anything less carries the grave risk of spreading cellulitis, septicemia, and gas gangrene, and, in any case, a wound unfit for early suture. Penicillin and sulfonamides are not substitutes for surgery—they are valuable adjuncts.

Nothing less than excision of contamination is safe, but this does not mean block excision. A wide area of skin around the wound was washed with soap and water and shaved, and usually some spirituous solution was applied. Because of the value and the viability of skin, the practice of removing a rim of about one-eighth of an inch was abandoned, only the frayed edge was removed. In order to inspect the depths of the wound it was extended sufficiently to permit the insertion of retractors down to the bottom. This necessitated generous longitudinal incisions of the deep fascia, which had the added advantage of decompressing edematous, congested tissues and reducing the incidence of vascular spasm, for the same reason transverse incisions also were sometimes employed. There was no fear of making incisions too long since they were to be sutured at the lines of communication, or at the Base in a few days. Tags of fat or fascia, or any soiled area of either, were removed. All muscle that did not bleed or contract when cut was excised. Imperfect removal carries with it the danger of sepsis which would nullify the general policy of delayed primary suture. Search was made for pieces of indriven clothing and other foreign bodies, and these, together with any readily accessible fragments of metal, were removed. All spaces that might harbor pus were laid open. Until the last year of the war, pieces of bone wholly detached from periosteum were removed, but, as already recorded, it was discovered that in the presence of adequate penicillin this was no longer necessary. The operation was completed by insufflating penicillin-sulfonamide powder until there was a heavy frosting. The wound was not picked. Vaseline gauze with 5 per cent sulfonamide was popular at first, but once conditions were suitable for a general policy of delayed suture, under which regime the first dressing was performed at operation, the vaseline pack was replaced by a dry gauze dressing. In relatively superficial through-and-through wounds the practice was to lay open the tract, but when the penetration was deep it was the custom to treat each wound separately. Quite apart from fractures, every wound involving muscle was found to require splinting, and this had to include the joint below the wound. Finally, following surgery, no inspection of the wound was made until the patient reached the operating room where the delayed suture was to be performed. In the absence of pain or toxemia any exposure of the wound prior to this was meddlesome and led to superimposed infection.

These principles of treatment applied equally to all soft tissue wounds, whether of the limbs (with or without fractures), chest wall, back, axilla, or belly wall, although when it was essential to hold certain cases for from 8 to 10 days in the forward areas for medical reasons, as for instance abdominal cases, primary suture of such wounds was employed. The basis of the rule is the fact that stitched wounds and ambulance journeys are incompatible.

The whole plan of the policy of delayed suture was aimed at the suture of wounds within 3 to 5 days

after the original excision, and treatment in forward areas became so efficient that suture could be accomplished safely in over 90 per cent of the cases, with complete healing by first intention in from 83 to 93 per cent. Experience showed that this time factor was essential, for when casualties could not be delivered for delayed closure in less than 8 or 10 days after the first operation, the proportion of successes fell from 5 per cent to 10 per cent lower. In one theater of war, during the quietude of the winter of 1944 to 1945, an experiment in primary suture in the forward area was carried out. The criteria for selection were that wounds should be not more than 12 hours old and that they should be essentially superficial, that is, although the muscle might be involved, every part of the wound was exposed and therefore no nooks and crannies were present. Such wounds were usually tangential, although several were from 6 to 8 inches long and about 2 inches in depth. Two surgeons were selected to do this work and the cases were carefully observed. The usual excision technique was employed but the wounds were sutured at the end of the operation. Altogether, 140 patients, representing 180 wounds, were treated. Of these, over 90 per cent healed perfectly after 8 or 10 days and 70 per cent returned to duty within 17 days. There were no serious failures. The 10 per cent that were not healed when stitches were removed were either moist or there was a stitch abscess and part of the wound broke down. Since the patients were under constant supervision no untoward results followed. Two of the wounds which broke down were situated over bone, and this location came to be regarded as a contraindication to primary suture. The conclusion was that primary suture should be used only in specially selected cases when it can be assured that the patients can be held for 8 or 10 days until the stitches have been removed. It is, therefore, restricted to periods of inactivity. One of the great achievements of the policy of delayed suture was that scar tissue was reduced to a minimum, with primary suture it was eliminated.

There was no doubt that in penicillin we possessed an agent that no other bacteriostatic or antiseptic equalled. When penicillin became plentiful, wounds behaved in a manner hitherto unknown. The mortality rate from gas gangrene dropped to about 10 per cent. Almost all wounds were suitable for treatment by delayed primary suture, with an expectation of healing by first intention in well over 90 per cent. Gunshot wounds of bones were converted into closed fractures within a few days, it was no longer necessary to remove pieces of bone detached from the periosteum, they became incorporated into the developing callus. The incidence of empyema in the last 200 chest cases was only 2.5 per cent. Penicillin made possible these triumphs.

Vascular injuries. Of 36 ligations of the popliteal artery, 26 required amputation above the knee joint, and of 31 ligations of the femoral artery, 21 required amputation above the knee. Given a wound in the lower third of the thigh, the popliteal space

being full and tense, and the condition of the limb below the knee pointing to vascular embarrassment manifested by coldness, swelling, numbness, and the absence of pulse at the ankle, exploration was deemed the safest line of action. The wound was treated in the usual manner, but as the clot was being evacuated from the popliteal fossa the artery, whether completely or partially severed, usually began to bleed anew. In the completely cut artery, ligation of each end was carried out. Sometimes a partially divided artery was successfully sutured. Even when suture of a partially divided artery was possible, thrombosis usually took place. However, when the calf or forearm muscles became swollen and woody hard, with the flexors in contracture, the skin cold, insensitive, and mottled, and with absent pulses, such changes were irreversible and amputation above the knee or the elbow was necessary.

An important point in the management of cases of ischemic necrosis of muscle resulting from prolonged application of a tourniquet was to avoid removal of the tourniquet, since experience showed that this permitted an overwhelming dose of myotoxin to enter the circulation rapidly. Amputation should be above the tourniquet, a second higher one can be employed to control hemorrhage in the operative area if thought necessary.

Patients that developed vascular aneurysms were sent to vascular injury centers. Experience suggested that waiting for the development of an aneurysm after injury to the main vessel was the best way to save the limb.

Measures which were used to safeguard the peripheral circulation were nonremoval of the patient until the fate of the limb was clear, keeping the affected limb cool by elevating and uncovering it and by the use of an electric fan, and the application of electric heaters to the trunk to encourage vasodilatation. Paravertebral blocks or sympathectomy were not practiced to any extent. Another lesion that threatened the vitality of the limb was traumatic vasospasm, or thrombosis of the main artery resulting from concussion or bruising by a missile having passed nearby.

Injuries to the peripheral nerves Rough tests for voluntary movements and sensation were made in all limbs injured and the findings recorded. Until the last few weeks of war primary suture of cut nerves was discouraged and no attempt was made to rectify the situation until several weeks later at the Base. This policy was based on the knowledge that nerve suture in the presence of infection was doomed to failure, but when the ends of severed nerves were seen during operation, they were often connected loosely by a solitary stitch as a guide for future intervention. During the last period of the war, with penicillin plentiful, surgeons began formal nerve suture at the time of the delayed suture. This would save much time, and it promised success since not only did the technique give clean wounds but the early closure eliminated the formation of scar tissue, the nerve would then lie in a bed of normal tissue.

Amputations Early in the war, before the policy of routine delayed suture of all wounds became a practical proposition, the tendency was to save as much of the limb as was viable, and leave it to the surgeons at the Base or in the United Kingdom to perform a secondary and definitive amputation suitable for prosthesis. With growing experience the Syme and Stokes-Gritti procedures were largely abandoned and surgeons conformed to the principles laid down between the wars by limb-fitting surgeons. After penicillin became available amputations performed in the forward areas were suitable for delayed suture within 5 days and healed by primary intention. It became necessary to plan primary amputations as definitive ones. Broadly speaking, two amputations for both the upper and lower limbs were dictated by the form of prosthesis provided by the Ministry of Pensions. This was of the bucket type of artificial limb, with circumferential weightbearing. The two sites advocated for the upper limb were below and above the elbow. The best site below the elbow was 3 inches above the wrist, and the shortest stump that would support an artificial limb had to have at least 1 inch of ulna beyond the biceps insertion with the elbow flexed. In the above-elbow amputation the site of selection was 3 inches above the joint, and not less than 1 inch of humerus below the anterior axillary fold would control the socket of the artificial limb. For the below-knee amputation the tibia was 5½ inches from the line of the knee joint, although 4 to 2 inches was of any use. Above-knee amputations should be through the lower third of the thigh, or about 10 inches from the tip of the greater trochanter. The shorter the femoral stump the less adductor power remained, and anything less than 4 inches required a tilting-table limb. Following a coneshaped amputation with abundant skin flaps, with or without crushing of nerves, the flaps were left wide open, penicillin powder was insufflated, gauze dressings were applied, and the stump was splinted. After 2 or 3 days the amputee was evacuated to a "delayed suture center," and after suture one anticipated healing by first intention in over 90 per cent of the cases.

Joint injuries In the early days of war wounds, the wounds of the major joints were rightfully regarded as serious lesions because even when the limb was saved it was at the price of a stiff joint resulting from sepsis. After the importance of thorough surgical toilet was established, improvement followed and with penicillin the number of stiff joints became far less. The wound was excised in the usual manner, and the rent in the capsule was enlarged sufficiently for exploration of the joint cavity. Loose pieces of cartilage or bone and foreign bodies were removed. Blood clot was washed out. The capsule was closed when possible, and a solution containing 25,000 units of penicillin was injected into the joint cavity. The skin incision was left wide open and the wound dressed with gauze. The limb was then put up in plaster, extension being applied when possible. In

the case of the knee joint, the Tobruk splint was used, and as long as the extension was adjusted at frequent intervals, these patients traveled very well. In cases in which the patella or the olecranon process was badly comminuted, it was usual to excise the fragments.

Fingers and toes It was important to apply splints to the hands and feet in such a manner that the fingers and toes remained free, and to encourage activity from the beginning. This guarded against adhesions and mutilated against crippling stiff digits. When possible the wrist was also left free, but in cases of musculospiral involvement it was put up in dorsiflexion. This was also practiced when the flexor muscles or the tendons of the wrist and fingers were cut, as otherwise contracture was likely to occur. Even in hand wounds fixation was reduced to a minimum and active and passive movements of the fingers started as soon as possible.

Splinting for fractures was *sine qua non*, but from what has already been said in regard to the hazards of transportation, adequate immobilization is vital in wounds of the soft tissues. For first aid work, Thomas knee splints and Cramer wire were most commonly used. Extension was applied through a clove-hitch or a Milbank clip. The extension was tightened by a Spanish windlass which was checked often during transport. For postoperative splinting, plaster of paris was invariably used and even padded plaster of paris was a hazard. There-fore, every plaster splint was padded and all except the Tobruk type were split before evacuation. The thoracobrachial splint, binding the upper limb to the trunk, was the favored splint for evacuation when the bones involved were those of the shoulder, arm, or forearm. For fracture of the forearm, a long plaster slab was molded to the posterior surface of the limb from the shoulder down to the metacarpophalangeal joints, and kept in position by encircling bands of plaster. This was fixed to the trunk by a light plaster jacket. The cast was split before evacuation.

Fractures of the femur, whether they were high, in the midshaft, or supracondylar, were treated by skeletal traction. Mobile, balanced skeletal traction was employed by introducing a Steinmann pin through the tibia at the level of the tuberosity, and attaching a pull of 15 pounds, which after 6 or 8 weeks was reduced to 10 pounds. The thigh and the leg were rested on a Braun's splint. The difficulty in high fractures was to control the flexion of the short upper fragment, it being necessary to bring the lower fragment into apposition with it. In midshaft fractures, skeletal traction was employed but the limb was cradled in a Thomas splint slung to a Balkan frame. In supracondylar fractures, in addition to the methods described, it was often necessary to insert a Kirschner wire through the proximal tip of the lower fragment and apply vertical traction to the lower fragment. Active knee flexion followed as soon as muscle control of the limb was present. In these cases, callus formation was often rapid and

union often occurred in about 8 weeks. The British favored and used closed reduction of fractures of the upper extremity, the leg, and foot, in almost all of the cases. Only in very exceptional instances was skeletal traction required. It was found that proper reduction of these fractures with adequate plaster of paris splinting gave very satisfactory results.

When penicillin became available the authors decided to plate a series of fractures which were considered suitable for this procedure. Plating must have a limited application because the majority of fractures are grossly comminuted and if there are more than three fragments it is unlikely that the plate can be fixed securely enough to hold the fragments in reduction or to render the fracture stable. To be effective the plate must be long and the screws must hold tightly in both cortices. In a consecutive series of 70 cases with missile fractures of the femur, only 16 were found to be suitable for plating. In some patients, the knee movement increased rapidly during the early stages of physical therapy, but except in a few instances the final range was usually less than that in patients treated by balanced skeletal traction. At the end of 3 months, the same proportion of closed wounds was found among the patients treated without internal fixation. Other complications of internal fixation were persistent sinus formation, requiring removal of the plate, and loosening of the plate with infection. The subsequent history of patients treated with internal fixation reveals that in the majority, the plates need to be removed because of persistent quiet infection and toxemia, and inevitably the plate is responsible for delayed union.

Skin grafting was used much earlier than in previous wars, even within a few days of the wounding. However, only under exceptionally favorable circumstances were skin grafts applied at the primary operation. At a later stage, even when drainage was still necessary, a large raw surface could often be reduced by grafting to little more than a sinus.

Osteoporosis Following Burns NEAL OWENS *Brit J Plast Surg*, 1949, 1: 245

Sudeck's osteoporosis was detected in 8 patients following first and second degree burns. Osteoporosis may be considered as a possible burn complication because of the acidosis, the negative nitrogen balance, the endocrine imbalance, and the other metabolic disturbances associated with burn trauma. The diagnosis of osteoporosis is rendered difficult in burn patients because of bone pain, muscle atrophy, edema, and disuse of the involved extremity. X-ray examination of the involved bones shows irregular areas of rarefaction and progressive decalcification. Secondary infection complicating a burn is also a predisposing factor to osteomyelitis and spontaneous fracture.

Although the cause of bone atrophy is not definitely established, it is believed to be due to trophic neurosis or chemical biological changes in skeletal

calcium Meticulous care of the metabolic balance involving nitrogen, calcium, and phosphorus must be observed in the treatment of burn cases Prompt skin coverage so as to allow for early motion is also requisite for the prevention of osteoporosis Surgical or chemical sympathectomy is not indicated for this type of osteoporosis

BENJAMIN G P SHAFIROFF, M D

Some Observations of Curling's Ulcer F BRAITHWAITE and P H BEALES *Brit J Plast Surg*, 1949, 1 284.

Curling's ulcer is an ulceration of the duodenum following extensive burns of the body surface The development of infection in the burned areas is a likely factor in the cause of such ulcers because their incidence has considerably decreased since the advent of penicillin These lesions also occur with other septic conditions

Two cases are reported In the first, the burns involved 65 per cent of the body surface and hematemesis started on the tenth hospital day This continued intermittently until death about 10 days later, despite blood transfusions Autopsy revealed an ulcer of the duodenum 4 cm in length which had eroded into the gastroduodenal artery In the second case, severe burns of the hand were followed in a week by abdominal pain before meals, and in 3 more days hematemesis and melena developed These continued till the patient was in shock Continuous blood transfusion was necessary and laparotomy revealed a duodenal ulcer similar to that in the previous case A partial gastrectomy was performed and an uneventful recovery followed

These ulcers grow rapidly in width and depth and there was no indication of repair in either of the cases presented, which suggested that when extensive hematemesis or melena occurs 1 or 2 weeks following surface burns, surgery is indicated Immediate medical measures are urged for any signs of abdominal distress following such burns

STANLEY W TUELL, M D

ANESTHESIA

Studies of the Circulation of Anesthetized Patients by a New Method for Recording Arterial Pressure and Pressure Pulse Contours KENNETH F EATHER, LYSLE H PETERSON, and ROBERT D DRIPPS *Anesthesiology*, 1949, 10 125

A practicable method for the recording of direct arterial pressures involves insertion of a small plastic catheter into a brachial artery Pressure changes are recorded by connecting the catheter to a capacitance manometer This method supplies accurate beat-to-beat pressure readings, pulse rate, and evidence of changes in the cardiac output and peripheral resistance as they occur

Direct recordings from approximately 100 patients during anesthesia and surgery have demonstrated their practical value in supplying a knowledge of alterations in the circulation Such information can

be of value to measure such phenomena as the circulatory effects of traction and visceral manipulation during operation, abnormal cardiac rhythm and force of cardiac contraction, the effect of posture on the circulation, the circulatory action of drugs commonly used by the anesthesiologist, and the effect of changes of pressure within the respiratory tract

The method is recommended as an adjunct to the study and evaluation of patients subjected to anesthesia and surgery It is of particular value when patients are considered poor risks, during pulmonary and cardiac operations, and during the development of new surgical techniques

MARY FRANCES POE, M D

Convulsions Under Anesthesia in Children STANTON BELINKOFF *Current Res Anesth*, 1949, 28 40

Convulsions under anesthesia present a serious problem If allowed to continue, a severe degree of anoxia, permanent brain damage, or death may result

The immediate treatment of choice is the slow intravenous administration of a 2.5 per cent solution of sodium pentothal If venipuncture is impossible, 20 c.c. of pentothal should be given rectally Curare is another agent that may now be added to the list of useful drugs in combating this complication When it is impossible to perform a venipuncture to administer the curare, it may be given intramuscularly, even though the effect of the drug may not be apparent for several minutes

The patency of the airway must always be assured Oxygen should be administered continuously, if necessary, by artificial respiration or intratracheal insufflation

MARY FRANCES POE, M D

Pathologic Findings in Some Deaths during Anesthesia KEITH BOWDEN *Med J Australia*, 1949, 1 86

An analysis is made of the last 50 unselected deaths under anesthesia which occurred in Melbourne on the operating table, before operation was commenced or completed, or in the postoperative period before the patient recovered from the anesthetic. The group serves chiefly to emphasize that insufficient regard for the well established principles in the administration of anesthetics sometimes leads to disaster The analysis is given in table form and the relevant facts are tabulated as far as they could be gathered for each case The cases are divided into five categories

- 1 Deaths caused by the disease for which the operation was designed and the anesthetic given
- 2 Deaths resulting from disease present, apart from the disease for which the operation was undertaken
- 3 Deaths directly due to the anesthetic
- 4 Deaths due to the operative procedure, shock, or hemorrhage
- 5 Deaths due to the complications of anesthesia, such as the inhalation of vomitus

Much information of practical value emerged from the study of these cases. The time-honored practice of waiting until 4 hours have elapsed since the last meal and then giving an anesthetic under the impression that the stomach will be empty, has led to many fatalities. One patient had no solid food for 28 hours preceding anesthesia and died from asphyxia from inhaled vomitus. The fact that asphyxia can and does occur in the absence of frank cyanosis was stressed. Also, the use of a laryngoscope, bronchoscope, and suction might prove a life-saving measure, as might laryngotomy or tracheotomy with efficient suction.

The more thorough the postmortem examination the less does one have to fall back on status lymphaticus as the cause of death. It is not very well known that laryngospasm in the induction stage may be fatal, a fact that should make the anesthetist pause before he proceeds to pour on more anesthetic to get the patient over a spasm.

Twenty-seven of the deaths may be regarded as having been theoretically preventable, 14 of them showed typical asphyxia as their cause. After completion of an operation on the nose, throat, or mouth, the patient should be turned on his side and put to bed in this position until he has recovered from the anesthetic, and no patient should be removed from the operating theater if he presents any traces of cyanosis.

The author concluded that there is a certain amount of risk with every anesthetic administered and that that risk can be made only the irreducible minimum when due regard is paid to the well established principles governing the administration of anesthetics and the immediate after-care of the patient.

MARY LARP, M D

The Effect of Vasoconstrictors Upon the Duration of Spinal Anesthesia. A Controlled Study in Man. KENNETH C. BRAY, SIDNEY KATZ, and JOHN ADRIANI. *Anesthesiology*, 1949, 10: 40.

The use of a vasoconstrictor in local anesthetic solutions for infiltration or block anesthesia has long been accepted technique, but the use of these agents intrathecally for prolongation of spinal anesthesia has not been widely accepted. Cullen studied the effect of a vasoconstrictor with procaine for spinal anesthesia, and the authors have studied the action of nupercaine and pontocaine with several different sympathomimetic drugs added. The study was unusually well controlled, for every patient received at least two spinal anesthetics of the modified saddle block type. One group of patients received no vasoconstrictor in either of the anesthetic mixtures, while other groups were given first one injection without vasoconstrictor and later another anesthetic employing the anesthetic drug with some sympathomimetic agent. The vasoconstrictor agents studied were epinephrine, neosynephrin, ephedrine, and oenethyl.

There were variations in the duration of anesthetics given to the same patient, regardless of whether or not a sympathomimetic agent was em-

ployed. However, the figures used for comparison represented the average durations, and significant results were obtained. With nupercaine and vasoconstrictor, the average difference in duration of anesthesia was an 0.38 per cent increase, which is not significant, and the average durations of anesthesia were altered the following amounts by the different sympathomimetic agents: ephedrine, 50 mgm, a decrease of 4.9 per cent; neosynephrine, 5 mgm, an increase of 8.0 per cent; epinephrine, 1 mgm, an increase of 36.2 per cent. With the use of pontocaine without a vasoconstrictor, the average difference in duration of anesthesia was 2.3 per cent decrease, and the average durations of anesthesia were altered the following amounts by the different sympathomimetic agents: ephedrine, 50 mgm, an increase of 6.68 per cent; neosynephrin, 5 mgm, an increase of 8.15 per cent; oenethyl, 100 mgm, an increase of 1.6 per cent; epinephrine, 1 mgm, an increase of 61.56 per cent.

There were 10 significant rises in blood pressure and 15 significant falls in blood pressure during anesthesia in a total of 341 anesthetics. No delay was noted in the onset of anesthesia when a vasoconstrictor was combined with the spinal anesthetic drug.

The authors concluded that changes occurring with ephedrine, neosynephrin, and oenethyl were not clinically significant. Epinephrine proved to be the only vasoconstrictor which prolonged the duration of anesthesia appreciably with either pontocaine or nupercaine. No neurologic complications or sequelae were noted in any cases.

R. GIBSON PARRISH, M D

Anatomic Reasons for Caudal Anesthesia Failure.

M. GENE BLACK. *Current Res Anesth*, 1949, 28: 33.

The literature on caudal anesthesia leads one to believe that a persistent percentage of failures occur even in the hands of experienced anesthesiologists. This study was undertaken to determine some of the reasons for these failures and, if possible, to aid in their prevention.

In reviewing the osteology of the sacrum, we find adequate reason for many of the anatomical defects found in 104 sacra. Fifteen and three tenths per cent showed defects which made successful caudal anesthesia improbable. Absent hiatus, complete agenesis and bony septum, together with 3 cases in which spinal anesthesia appeared inevitable because of distortion, made up this group. Of the total number of sacra with defects, those showing absent hiatus appear to represent the basic minimum of failure, or 7.7 per cent.

In those cases in which caudal anesthesia is considered essential for the safety of the patient, it is suggested that x-ray studies of the sacrum will provide a valuable means of combating failure, as in many cases anesthesia may be possible but difficulties may be experienced because of the presence of structural changes and defects.

MARY FRANCES POE, M D

SURGICAL TECHNIQUE

The Therapeutic Uses of Intravenous Procaine DAVID J. GRAUBARD and MILTON C. PETERSON *Anesthesiology*, 1949, 10: 175

The results in the management of 448 cases in which 1,954 intravenous procaine infusions were given have been evaluated, and it is concluded that this technique should be considered as an adjuvant to the treatment of selected traumatic, inflammatory, and spastic conditions.

The importance of vitamin C therapy cannot be overemphasized. It is suggested that vitamin C be given prior to the use of large doses of procaine to increase resistance to toxic side effects, particularly in patients in a poor nutritional condition. There is evidence that interference with the reflex arc which is established following trauma will hasten the recovery and rehabilitation of the injured individual.

The intravenous administration of procaine, in conjunction with vitamin C, in the treatment of arthritis has given some promising results, and improvement noted in spastic conditions of neurologic origin recommends this form of therapy for further clinical study. MARY FRANCES POE, M.D.

Anesthesia for Neurosurgical Procedures: Analysis of 1,000 Cases C. R. STEPHEN and A. PASQUET *Current Res. Anesth.*, 1949, 28: 77

The authors review 1,000 consecutive operations performed at the Montreal Neurological Institute from July, 1946 to September, 1947 and discuss some of the problems encountered. General anesthesia was employed in 700 cases. In all of these, a patent airway was maintained by means of an endotracheal tube. Premedication for craniotomy consisted of atropine alone because of the dangers of morphine in patients with increased intracranial pressure. In other cases demerol or morphine was added. An avertin basal anesthetic was often used to allay fear in patients. This was followed by induction with ether by the closed or open method. In the majority of cases smooth induction was accomplished with small amounts of pentothal followed by gas or gas ether and intubation under direct vision. Packoffs of vaseline gauze were used almost entirely, liberally coated with 2 per cent nupercaine water-

soluble ointment. A description of the sponge rubber pad for supporting the chest in the prone position is included. Maintenance was attained by the use of ether-air anesthesia, with a nonresistant, non-breathing valve close to the endotracheal tube.

As an alternative, 123 patients with a nonbreathing valve and large flows of gases of from 8 to 10 liters per minute. This combination was found satisfactory for procedures lasting up to 2 hours but in longer operations it was common to find the development of an increased pulse rate and a decreased pulse pressure. No abnormal increase in intracranial pressure was noted with this technique.

A series of 211 patients received spinal analgesia for the removal of intervertebral discs, 1 to 1500 nupercaine was the agent used and the procedure was described in detail. Only in the semicomatose and the poor-risk patient was local analgesia used without supplement, and nupercaine in 1 to 125,000 1 to 4000 dilution with epinephrine in 1 to 125,000 dilution were the agents of choice. For arteriograms general anesthesia was employed and a deep plane of anesthesia was established during the period of manipulation to avoid troublesome reflexes from the carotid sinus. Fluid replacement was considered an important responsibility of the anesthetist. Only in sympathectomies was blood purposely withheld because in these cases a somewhat decreased blood flow was beneficial to the patient whose blood pressure was being substantially reduced by the operation. Analeptics were rarely used during intracranial operations under general anesthesia, but were of value in patients under spinal analgesia. To control restlessness under spinal analgesia, the intravenous use of nembutal was found most effective.

Complications during the induction of anesthesia were few. During operation a rapid fall of the blood pressure and a weak pulse were the most common abnormality. Two patients had severe blood reactions. Postoperative complications were not common. There were 67 deaths, 3 of which occurred in the operating room and the patients were children. Fifty of the 67 patients had received general anesthesia. MARY KARP, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

The Diagnosis of Chronic Subdural Hematoma in Children and Adolescents J W D BULL. *Brit J Radiol*, 1949, 22 68

In chronic subdural hematomas of adults, pneumography presents certain constant features, but angiography alone can firmly establish the diagnosis prior to operation. In children and adolescents the skull is more malleable and, therefore, a correct diagnosis can often be made by roentgen examination without the use of contrast media. The subdural hematoma in newborn infants is not discussed by the author.

The material consisted of 15 cases, 13 of which were confirmed. The patients varied in age from 20 months to 20 years and fell into the following three distinct groups: group 1, with appearances similar to those seen in adults, i.e., negative findings in ordinary roentgenograms and characteristic positive findings on pneumography (3 cases); group 2, with definite pathognomonic changes in ordinary roentgenograms (9 cases); and group 3, with calcified hematoma and hemiatrophy of the affected side of the skull shown in ordinary roentgenograms (3 cases).

The main features of the 15 cases are summarized and arranged in a table.

Group 1 The 3 patients belonging in this group were 1, 11, and 15 years old, respectively. In the baby of 1 year the hematoma was encountered when the burr hole was made for ventriculography. In the other 2 cases ventriculograms showed the typical deformity seen in adults.

Group 2 The ages in this group of patients varied from 4 to 18 years. The important roentgen findings were (1) bulging of the middle fossa on the affected side, shown in the lateral and submentovertical view, (2) elevation of the lesser wing of the sphenoid, shown in the posteroanterior view, and (3) bulging out of the greater wing of the sphenoid, likewise shown in the posteroanterior view. Dyke and Davidoff described three additional signs which were not confirmed by the author. These were (4) atrophy of the superior and lateral wall of the superior orbital fissure, (5) hypertrophy of the frontal and ethmoidal sinuses on the affected side, and (6) thickening of the skull.

Emphasis is laid on the proper technique of roentgenography. Exposures are usually made in 5 views: right lateral, left lateral, frontal (posteroanterior) with a 25 degree tilt of the rays toward the feet to show the orbits, occipital with 35 degree tilt of the rays, and basal (submento vertical) view. The techniques of taking the frontal and basal views are described in detail.

In the author's series the time interval between the trauma and the roentgen demonstrability of the bulg-

ing of the skull was 3 months. Hardman reported the case of a boy aged 8 who had a bulging middle fossa 10 weeks after a head injury, while A. Schuller thinks that no more than 6 weeks are necessary for this sign to appear.

Group 3 The 3 cases in this group pathologically represent the end result of untreated hematomas in which calcification or ossification has occurred. They are described in detail. Two cases also showed a hemiatrophy of the skull on the side of the calcification which was parietotemporal in position. There was a marked displacement of the sagittal sinus to the affected side of the head and encephalography showed that the septum pellucidum was also displaced, which signified concomitant hemiatrophy of the brain.

The general conclusion is drawn that ordinary roentgen examination of the skull can provide the diagnosis in most cases of chronic subdural hematoma in children and adolescents and thus enable the surgeon to carry out a relatively minor curative operation.

T. LEUCUTIA, M.D.

The Roentgenologic Features of Neurofibromatosis

JOHN F. HOLT and EDWIN M. WRIGHT. *Radiology*, 1948, 51 647

Neurofibromatosis or von Recklinghausen's disease is characterized by multiple tumors of the peripheral nerves associated with areas of pigmentation in the skin. Less frequently an involvement of the central nervous system and of the skeleton may also occur.

The authors reviewed the findings in 127 cases of neurofibromatosis seen at the University of Michigan Hospital between 1934 and 1947, paying particular attention to the osseous manifestations. They were surprised by the frequency, variety, and yet consistency of the patterns encountered in these lesions. Slightly over 29 per cent of the total group showed some form of a skeletal defect, but these defects must have been more numerous as in 50 cases no roentgenograms were available. The bone changes were placed into 6 categories.

1 **Erosive changes** Norgaard described these changes as the "pit or cave" due to erosion of the bone by an adjacent neurofibroma. While such defects are characteristically observed in the bones of the extremities, the authors encountered 2 cases in which neurofibromas of intercostal nerves produced bilaterally symmetrical notching of several ribs, which somewhat resembled the roentgen appearance of coarctation of the aorta.

2 **Scoliosis** This was the most frequent osseous defect occurring in conjunction with neurofibromatosis. It may be due to a coexisting anomalous development of one or more vertebrae or to a compensatory function in overgrowth or undergrowth of a lower extremity. It occurs most commonly in the

lower dorsal region, consisting of kyphoscoliosis, with the kyphotic element predominating, but the authors also observed cervical kyphosis of varying degrees of severity

3 *Disorders of growth* Among these, overgrowth of one or several bones constituted the most ordinary finding. The overgrowth in the majority of the cases was longitudinal as well as circumferential, but rarely an actual diminution in the caliber with increase in the length of the bone was also found. It is significant that in all growth disturbances an elephantiasis neuromatosa of the soft tissues was present, which could easily be identified in the roentgenograms and was a helpful point in the differential diagnosis.

4 *Congenital bowing and pseudarthrosis of the lower leg* The frequent association of neurofibromatosis and congenital bowing of the tibia (with subsequently developing pseudarthrosis) is generally accepted. However, considering the fact that neurofibromas first appear at puberty or later in life, the question arises whether a congenital bowing of the tibia may always be conceived as a precursor of von Recklinghausen's disease. The authors observed 1 case in which the sequence of events seems to lend support to the theory.

5 *Intraosseous cystic lesions* The presence of cystic lesions is often encountered in all stages of neurofibromatosis. Apart from the subperiosteal cyst, which seems to be an established entity, the authors have found a number of cystic lesions within the cortical and cancellous bone. In some instances the lesions were located in the distal metaphyses and suggested localized fibrous dysplasia.

There were 2 cases in the authors' series which were most remarkable. In one, that of an infant 4 months old, a clinical and histologic diagnosis of neurofibromatosis was established. Roentgenograms of the skeleton revealed multiple cystic lesions of the metaphysis of many of the long bones. Thirteen months later the osseous changes had completely disappeared. In the other case, likewise that of an infant with innumerable subcutaneous tumors and very extensive bone changes, biopsy of the soft tissues demonstrated neurofibroma but three biopsies from bone failed to show the presence of a similar tumor. Therefore, the authors think that a relationship between neurofibromatosis and fibrous dysplasia may exist, although Jaffe has denied any such link.

6 *Associated anomalies of the skeleton* These include spina bifida, fusion of the vertebral bodies, congenital dislocation of the hips, clubfoot, and other similar anomalies. In 1 patient symmetrical anomalies of the hands and feet were noted. In 2 cases the involvement of the eyelids and orbital soft tissues was associated with orbital wall defects.

The general conclusion is drawn that von Recklinghausen's disease is not a rarity and that the incidence of bone involvement is considerably greater than the figure of 7 per cent commonly quoted in the literature.

The Detection of Gastric Carcinoma by Photofluorographic Methods I Introduction II Equipment Design JOHN F. ROACH, ROBERT D. SLOAN, and RUSSELL H. MORGAN *Am J Roentg*, 1949, 61: 183, 188

A study has been established at the Johns Hopkins Hospital, Baltimore, to determine the efficiency of examination for carcinoma of the stomach of all patients above the age of 40 who are admitted to the Dispensary Out-Patient Clinic of the Hospital by use of a photofluorographic unit. The study will be pursued for a period of 5 years. It has been statistically shown that cancer of the stomach is a prevalent and rapidly fatal disease for which the only promising form of therapy is early surgery. The equipment employed for these examinations consists of a standard 200 milliamper generator, a rotating anode tube, and a grid-screen camera assembly using a Patterson type E-2 screen and a Schmidt camera. The grid-screen camera assembly is mounted beneath a horizontal roentgenographic table to permit the examination of patients in the recumbent position. The nucleus of the installation is a 70 mm Schmidt camera, constructed by the Danish engineer Helm. Results of the use of the equipment in the early detection of gastric carcinoma will be reported in subsequent articles.

FRANK L. HUSSEY, M.D.

The Early Diagnosis of Acute Septic Osteomyelitis, Periostitis, and Arthritis, and Its Importance in the Treatment SIGVARD JORUP and SVEN ROLAND KJELLBERG *Acta radiol*, Stockh, 1948, 30: 316

The author emphasizes the importance of early diagnosis of acute septic osteomyelitis, periostitis, and arthritis.

The first roentgen sign of an acute septic osteomyelitis is the appearance of edema of the soft tissues at the site of the disease. This is manifested by a swelling of the surrounding muscles, and by blurring or obliteration of the fatty intramuscular septa. Engorgement of the vessels also appears in the subcutis. In a somewhat later stage, edema of the subcutis, which results in this layer appearing more indistinct and becoming broader than on the healthy side, is sometimes noticed as well. If the change affects a joint, a distention of the soft tissues of the joint with possibly an increase in the amount of fluid in the joint, can often be noticed. The changes in the soft tissues begin early. In acute septic coxitis, not infrequently an infiltration is observed in the soft tissues on the inner side of the pelvis. One can then observe on the diseased side a more or less increased breadth of soft tissue shadows proceeding down and along the inner edge of the pelvis. Roentgenograms showing a higher degree of contrast of the different soft tissue structures are necessary. Low radiation, varying between 35 and 45 kilovolts, and greater focal distance are necessary to produce roentgenographs of this type. The authors present 5 cases which demonstrate the value of soft tissue films.

Polyostotic Fibrous Dysplasia (Albright's Syndrome) and Its Comparison with Dyschondroplasia (Ollier's Disease) A Correlation of Roentgenological and Pathologic Findings
L. R. SANTE, WM. BAUER, and R. M. O'BRIEN
Radiology, 1948, 51: 676

Polyostotic fibrous dysplasia was described in the earlier literature as a variant of osteitis fibrosa cystica (von Recklinghausen's disease). In 1937, Albright, Butler, Hampton, and Smith reported 5 cases, suggesting for the first time that the syndrome represents a distinct entity. In 1938, Lichtenstein differentiated the condition from other diseases with which it was confused and recommended that the name of polyostotic fibrous dysplasia be used for its designation.

The authors present 4 cases and discuss the clinical, roentgenologic, and pathologic features of the syndrome as well as the differentiation from cystlike lesions and Ollier's disease.

Clinically, fibrous dysplasia of bone has an insidious onset, the osseous changes developing at a very slow pace. Often the condition goes unsuspected for years until there is interference with proper function or a pathologic fracture occurs. The diagnosis is usually made by roentgen examination.

The most important roentgen findings in the early stage are tiny cystlike areas within the cortical structure, often fusing with each other and giving the appearance of pseudoeexpansion. There is no evidence of periosteal elevation and osteoporosis does not occur. Later, the process leads to a shell like thinning of the cortex complicated by spontaneous fractures which, however, heal readily by new bone formation. Under certain conditions varying degrees of sclerosis of the involved bones may occur.

The bone lesions have a tendency to unilateral involvement but in the advanced stages both sides may become affected. They are often associated with pigmented areas of the skin and sexual precocity in the female.

The etiology is unknown. It was suggested that the condition may be due to a congenital disturbance of the activity of the undifferentiated fibrous bone-forming mesenchyme, or to damage of the region of the hypothalamus, or to an anomaly of the sympathetic system and the adrenals. The serum phosphatase is sometimes increased but the calcium-phosphorus balance is not disturbed.

Microscopically, there is an osteoclastic absorption of the bone structure followed by fibrosis of the bone marrow in the cortical and subcortical areas. The process starts in the haversian canals and spreads to the surrounding structures. Sometimes a moderate periosteal bone deposition is noted despite the absence of such a sign in the roentgenograms. Rarely, small islands of hyaline cartilage may be embedded in the characteristic tissue of polyostotic fibrous dysplasia.

In the presence of the extraskelatal lesions, the differential diagnosis from other cystlike diseases of the bone is easy.

The differentiation from von Recklinghausen's disease is based on the fact that the latter nearly always shows marked osteoporosis due to hyperparathyroidism. The bone deformity in polyostotic fibrous dysplasia is caused by weakening of the cortex secondary to local enlargement of the individual lesions. In the very advanced stage, however, a distinction between the two conditions may not be possible from a study of the roentgenograms alone. A correlation with the clinical findings and mineral metabolism, or a biopsy may prove necessary.

The differentiation from Ollier's dyschondroplasia has not been widely discussed in the literature. On roentgen examination, this condition shows characteristic rarefaction at the diaphyseal ends of the bones with areas of intervening decrease in density due to remnants of cartilage. Either one or several bones may be involved. There is no periosteal reaction or other sign of new bone formation. Microscopically, Ollier's disease shows cartilaginous proliferation remaining within the bony structure rather than fibrous replacement.

The 4 cases are presented in detail, numerous roentgenograms and some photographs being used to illustrate the characteristic features. The opinion is expressed that the condition undoubtedly occurs much more frequently than was formerly supposed.

T. LEUCUTIA, M.D.

The Subarachnoid Spaces of the Root Sheaths in the Lumbar Region
K. LINDBLOM
Acta radiol, Stockholm, 1948, 30: 419

Histological studies by Rexed revealed that the spaces adjacent to the root tips might form proliferations with cysts covered by a thin nervous tissue. In an effort to determine whether "Rexed cysts" were the same as widened endings of root sheaths as seen in myelograms, a roentgenographic and anatomic study of the lumbar root sheath was done on 35 specimens, and 150 myelograms were reviewed.

Anatomical studies revealed that the subarachnoid space varied with the length of the nerve root. Four specimens were injected with barium sulfate, subjected to roentgenography, and then cross sections, 1 mm thick, were made of the nerve root, dural sheath, and adjacent ganglia. The barium in the subarachnoid spaces might project to the ganglia. The latter ended in fimbrialike tips projected between the roots and root bundles and were interrupted by incomplete septa. Cysts that were present did not communicate with the subarachnoid space and were not demonstrable in myelograms. Differences in the shape, size, and extent of the dural sac were considered as variations of the normal.

Hip Lesions of Infants and Children Seen at the Newington Home and Hospital for Crippled Children
GILBERT W. HEUBLEIN, LOUIS BERNSTEIN, and B. J. HUBENET
Radiology, 1945, 51: 611

As an introduction to the subject, the authors give an excellent discussion of the embryology, anatomy,

and roentgen anatomy of the hip joint. In connection with the last they painstakingly analyze the different methods used to localize various landmarks which are so important from the point of view of early diagnosis, especially in infants.

The anatomical components of the hip in the newborn are largely cartilaginous, which fact renders many structures invisible on the roentgenograms. In addition, slight variation in soft tissue detail in an otherwise normal-appearing hip may point to the presence of infection. Timely recognition of such diseases as coxitis and osteochondropathy may mean the difference between a satisfactory end-result and a subsequent crippling deformity. An early diagnosis is also of considerable help in the treatment of congenital dislocation of the hip.

The authors reviewed 300 normal hips of children up to 6 years of age examined at the Newington Home and Hospital for Crippled Children. Their findings paralleled and corroborated those of Kleinberg and Lieberman.

For the purpose of description the diseases of the hip in infants and young children were classified in the following manner:

- I Dislocation
 - A Congenital
 - 1 Congenital dislocation
 - 2 Arthrogryposis
 - 3 Dislocation associated with or secondary to spina bifida
 - B Acquired
 - 1 Traumatic
 - 2 Septic
 - 3 Still's disease
 - 4 Poliomyelitis
 - 5 Subluxation in muscular dystrophy
- II Osteochondropathy (Legg-Perthes disease)
- III Congenital coxa vara and epiphyseolysis
- IV Rare lesions
 - A Myositis ossificans
 - B Achondroplasia
 - C Osteogenesis imperfecta

Every one of these diseases is discussed in considerable detail, illustrative case histories and some very unusual roentgenograms being presented. A bibliography of 78 articles is appended.

Sickle-Cell Anemia in Adults: Roentgenographic Findings

OMAR LEGANT AND ROBERT P. BALL.
Radiology, 1948, 51: 665

Sickle-cell anemia is a chronic hemolytic disease which occurs almost solely in the negro race. The condition was first reported by Herrick in 1904. Since then numerous other articles appeared in the literature dealing with various phases of this condition. It is now estimated that about 7 per cent of the negro population show the phenomenon of sickling (sicklelema) and that 1 or 2 per cent of these develop severe sickle-cell anemia.

The mortality rate from sickle-cell anemia is not known. Many of the affected persons die during

infancy and childhood but some complete a normal span of life. The terminal phase is characterized by extreme prostration, peripheral vascular collapse, and shock.

The authors studied the roentgen findings in 26 cases of sickle-cell anemia in adults seen at the Presbyterian Hospital in the city of New York since 1930. A postmortem examination was performed in 5 of the 26 cases.

The most frequent abnormal roentgen finding was enlargement of the heart (13 cases). There was no characteristic configuration and in the 5 autopsies no valvular lesion was found. The cardiac enlargement is thought to be the result of compensatory hypertrophy and dilatation in response to the long-standing severe anemia and anoxemia.

Next in frequency was generalized osteoporosis (11 cases). About one-fourth of all cases showed definite bone infarction. The bone lesions consisted of biconcave deformity of the vertebral bodies (4 cases), patchy cortical thickening of the long bones (7 cases), and localized bone infarcts, not unlike those seen in caisson disease (5 cases).

Four of the 26 cases showed nothing abnormal on the roentgenograms.

One unusual case is reported in detail. It showed an infarction of the body of a vertebra which was studied by means of serial roentgenograms, from its inception to healing 18 months later.

The clinical features and laboratory findings of the 26 cases are summarized in tabular form, and some very interesting roentgenograms are presented to illustrate the salient roentgen findings.

T. LEUCUTIA, M.D.

The Roentgenologic Changes in Sickle-Cell Anemia

STANLEY H. MACHT AND PAUL W. ROMAN.
Radiology, 1948, 51: 697

This article is based on a study of 48 cases of sickle-cell anemia observed at the Baltimore City Hospitals from 1936 to 1947. Twenty-nine of the patients were children under 14 years of age.

The most common findings were cardiac enlargement (76.2%), pneumonia (38%), coarsening of the trabeculae of the long bones associated with widening of the marrow cavity and thinning of the cortex (57.1%), similar changes in the short bones (35.2%), and the infarction type of destruction of the bone. After healing a roentgen appearance reminiscent of caisson disease is produced.

There is a definite time interval between the appearance of the clinical symptoms and the roentgen demonstrability of the bone changes. In 2 of the authors' cases the first roentgen examination, made soon after the onset of pain, swelling, and local heat of the affected area, remained negative, but a second examination made 3 weeks later showed evidence of bone destruction involving both the marrow and the cortex. Repair occurs after a long period of time.

If the thrombosis obliterates the blood supply near the articular surfaces, a permanent destruction of the joint may result. The authors observed 2 such

Polyostotic Fibrous Dysplasia (Albright's Syndrome) and Its Comparison with Dyschondroplasia (Ollier's Disease) A Correlation of Roentgenological and Pathologic Findings
L. R. SANTE, WM. BAUER, and R. M. O'BRIEN
Radiology, 1948, 51 676

Polyostotic fibrous dysplasia was described in the earlier literature as a variant of osteitis fibrosa cystica (von Recklinghausen's disease). In 1937, Albright, Butler, Hampton, and Smith reported 5 cases, suggesting for the first time that the syndrome represents a distinct entity. In 1938, Lichtenstein differentiated the condition from other diseases with which it was confused and recommended that the name of polyostotic fibrous dysplasia be used for its designation.

The authors present 4 cases and discuss the clinical, roentgenologic, and pathologic features of the syndrome as well as the differentiation from cystlike lesions and Ollier's disease.

Clinically, fibrous dysplasia of bone has an insidious onset, the osseous changes developing at a very slow pace. Often the condition goes unsuspected for years until there is interference with proper function or a pathologic fracture occurs. The diagnosis is usually made by roentgen examination.

The most important roentgen findings in the early stage are tiny cystlike areas within the cortical structure, often fusing with each other and giving the appearance of pseudoexpansion. There is no evidence of periosteal elevation and osteoporosis does not occur. Later, the process leads to a shell-like thinning of the cortex complicated by spontaneous fractures which, however, heal readily by new bone formation. Under certain conditions varying degrees of sclerosis of the involved bones may occur.

The bone lesions have a tendency to unilateral involvement but in the advanced stages both sides may become affected. They are often associated with pigmented areas of the skin and sexual precocity in the female.

The etiology is unknown. It was suggested that the condition may be due to a congenital disturbance of the activity of the undifferentiated fibrous bone-forming mesenchyme, or to damage of the region of the hypothalamus, or to an anomaly of the sympathetic system and the adrenals. The serum phosphatase is sometimes increased but the calcium-phosphorus balance is not disturbed.

Microscopically, there is an osteoclastic absorption of the bone structure followed by fibrosis of the bone marrow in the cortical and subcortical areas. The process starts in the haversian canals and spreads to the surrounding structures. Sometimes a moderate periosteal bone deposition is noted despite the absence of such a sign in the roentgenograms. Rarely, small islands of hyaline cartilage may be embedded in the characteristic tissue of polyostotic fibrous dysplasia.

In the presence of the extraskletal lesions, the differential diagnosis from other cystlike diseases of the bone is easy.

The differentiation from von Recklinghausen's disease is based on the fact that the latter nearly always shows marked osteoporosis due to hyperparathyroidism. The bone deformity in polyostotic fibrous dysplasia is caused by weakening of the cortex secondary to local enlargement of the individual lesions. In the very advanced stage, however, a distinction between the two conditions may not be possible from a study of the roentgenograms alone. A correlation with the clinical findings and mineral metabolism, or a biopsy may prove necessary.

The differentiation from Ollier's dyschondroplasia has not been widely discussed in the literature. Hip Lesions of Infants and Children Seen at the Newington Home and Hospital for Crippled Children GILBERT W. HEUBLEIN, LOUIS BERNSTEIN, and B. J. HUBENET *Radiology*, 1948, 51 611

As an introduction to the subject, the authors give an excellent discussion of the embryology, anatomy,

means of a two way petcock to a 20 c.c. Luer-Lok syringe, is introduced into the common carotid artery 1 or 2 cm caudad to the bifurcation. When the needle is in the artery some citrate solution already in the syringe is injected to prevent clotting of the blood in the syringe and needle, and then a syringe containing the diodrast is attached to the needle. The needle is directed laterally and downward so that the contrast media enters the internal carotid artery and not the external. While 15 c.c. of diodrast are being injected as rapidly as possible, the first exposure is made, the stereoshift is carried out, and a second exposure is taken. The author finds that this lateral stereoview is more valuable than a single lateral and a single anteroposterior view. The entire procedure requires great co-operation between the neurosurgeon and the radiologist.

JOHN W. HOPE, M.D.

Place of Deep External X-Ray Irradiation in the Treatment of Carcinoma of the Cervix by Long Element Needles
 GEORGE W. WATERMAN and
 WILLIAM A. REID *Radiology*, 1949, 52: 34.

The authors review their experience over a 10 year period (from 1933 to 1942) at the Rhode Island Hospital, Providence, Rhode Island, with the treatment of 347 cases of cancer of the cervix. One hundred and thirteen patients were treated primarily with radium needles alone, and 234 were treated primarily with radium needles and x-rays. The 5 year survivals in this group was 154, or 44.4 per cent.

In order to give a more accurate picture, comparisons between the two groups are made on the basis of similar clinical stages. The Schmitz classification was used. Stages 1 and 2 represent the operable or favorable group and stages 3 and 4 the inoperable and still purely radiological group.

In reviewing the statistics of the cases it is noted that 56 patients in stages 1 and 2 who were treated by interstitial radiation alone showed a 5 year salvage of 45, or 80.4 per cent. On the other hand, the salvage for a similar group of 77 operable patients treated by radium needles and x-ray irradiation was only 64.9 per cent, a difference of 15.5 per cent in favor of radium alone. In the inoperable or unfavorable group (stages 3 and 4) there was a 22.8 per cent survival for the 57 patients treated with needles alone and a 29.3 per cent survival for 157 patients receiving x-ray irradiation in addition to the radium.

The incidence of complications was markedly higher in the operable cases when x-rays were used with needles, being 22.1 per cent or more than twice that with needles alone (10.7%). In the inoperable group the gross incidence of complications did not vary so widely. The group treated with needles and x-rays showed fewer complications—12.1 per cent as compared with 14 per cent when radium alone was used.

The incidence of fistula in patients treated with needles alone was 3 in 113, or 2.7 per cent, occurring in patients with carcinoma of stages 3 and 4. In the patients treated with needles and x-rays the fistula

incidence was 13 in 234, or 5.6 per cent. Five of these had carcinoma in stage 1 or 2, an incidence of 6.9 per cent for these two stages. In 94 patients to whom x-ray therapy was given less than 1 month before or after radium treatment, the incidence of complications was 22.3 per cent as compared with a gross incidence of 12.3 per cent for all stages when radium was used alone. By increasing the interval to at least 8 weeks between the radium and x-ray therapy the complications were cut down. The use of a 4 cm. lead strip over the lower abdomen above the symphysis was found to reduce the x-ray overdosage to the paracervical area, which was considered responsible for some of the complications.

The x-ray factors used were 200 kv., 20 ma., target-skin distance 50 cm., filter 0.4 mm. of tin (Thoraeus). Two large fields (one anterior and one posterior) were used. The method of radium treatment consisted of using 2 and 3 mgm. needles (a total from 24 to 30 mgm. in early cases, and rarely more than 50 mgm. in late cases), and a 20 mgm. cervico-uterine application, gamma radiation, 0.5 mm. of platinum filter, and a long interval of 168 hours or 7 days.

The authors conclude that in making use of long paracervical and parametrial element needles, great caution should be used in stages 1 and 2 when x-ray radiation is given externally. The cervix and paracervical triangle should be shielded as much as possible. An interval of from 9 to 12 weeks after treatment with radium before use of x-rays gives the best results with regard to freedom from complications. In badly infected and more advanced cases preliminary x-ray therapy has its proper place.

FRANK L. HUSSEY, M.D.

RADIUM

Probable Trends in the Irradiation Treatment of Carcinoma of the Cervix Uteri with the Improved Expanding Type of Radium Applicator
 EDWIN C. ERNST *Radiology*, 1949, 52: 46.

The author presents an improved type of radium applicator to meet the problem of obtaining a greater degree of radiation effectiveness in the potential metastatic parametrial pelvic field, in the treatment of carcinoma of the cervix uteri. More effective and uniform irradiation is obtained by use of this radium applicator. The uniform spacing of multiple equal radium sources is not disturbed when the lateral capsules of this particular type of radium holder are expanded to pre-established fixed positions, irrespective of the anatomical size and shape of the vaginal vault or the extent of the malignancy.

The applicator is so constructed that in the closed position the transverse diameter measures less than 3.0 cm., which makes for ease of introduction. The lateral colpostats are expanded mechanically by use of a rotating knob on a handle which is detached after introduction, and the applicator is packed and fixed in the desired expanded position. The cervical stem of the applicator, when three longitudinal capsules are employed, is approximately 7 cm. in

cases, one with destruction of the wrist and the other with destruction of the hip.

Thromboses of the capillaries of the skin lead to chronic ulcers of long duration, especially at the ankles. The secondary infection which is common in these ulcers often produces periosteal changes in the underlying bone similar to those observed in varicose ulcers.

The poor nutrition of the tissues leads to general changes consisting of a linear habitus, emaciation, long extremities, short trunk, upper dorsal kyphosis, deep chest, protuberant abdomen, spider hands, and occasionally a slight turrecephaly. Abnormal dentition and delayed osseous union have also been found.

The authors have arranged all the roentgen changes in a tabular form which is as follows:

- 1 Roentgen evidence of involvement of the viscera
 - (a) Cardiac enlargement
 - (b) Pathological changes in the lungs
 - (c) Enlargement of the liver, cholelithiasis
 - (d) Enlargement of the spleen in children—possible calcification later in life
- 2 Skeletal changes due to hyperplasia of the erythroblastic elements
 - (a) Long bones
 - (1) Irregular trabeculation
 - (2) Widening of the medullary spaces
 - (3) Cortical thinning
 - (b) Short bones and flat bones
 - (1) Exaggeration of trabecular markings of the ilia, scapulae, phalanges
 - (2) Cupping of the vertebral bodies
 - (3) Skull Widening of the diploe, thickening of parietal and frontal bones, thinning of outer tables, and radial arrangement of trabeculae
- 3 Skeletal changes due to thromboses
 - (a) Long bones
 - (1) Cortical thickening
 - (2) Narrowing of medullary cavity
 - (3) Loss of bone tissue
 - (4) Periosteal reaction
 - (b) Short bones
 - (1) Necrosis and resorption of bone
 - (2) Periosteal reaction
- 4 Skeletal changes due to disturbances of growth

The Angiocardiographic Measurement of the Normal Great Vessels. CHARLES T. DOTTER and ISRAEL STEINBERG. *Radiology*, 1949, 52: 353

Recognizing a need for greater accuracy of measurement of the great vessels, Dotter and Steinberg have used angiocardiographic material in an attempt to establish some normal values. One hundred selected patients were measured at various specific sites, and the minimum, maximum, and average values for the series recorded.

The authors anticipate that a larger series of similar measurements will support their preliminary data. Those interested in this subject should consult the

original diagrams of sites measured and the tables of measurements.

PAUL W. EYLER, M.D.

The Aid of Arteriograms in the Diagnosis and Treatment of Intracranial Aneurysms. JAMES L. POPPEN. *Radiology*, 1949, 52: 347

This article is based on a series of 114 intracranial aneurysms occurring in 110 patients studied at the Lahey Clinic. In all but one of the cases the cause was presumably a congenital defect in the arterial wall. The 1 exception was found to be due to a mycotic embolism. Twenty-three of the patients were hypertensives and none of them had syphilis. In 63 cases the aneurysm occurred on the left side, and in 47 on the right side. Seventy-two of the patients were females and 38 were males. The majority of the symptoms occurred in patients between the ages of 20 and 60 years, the youngest being 14 years and the oldest, 70.

The symptomatology of this condition is variable and there is no definite clinical syndrome. The symptoms found in the 110 cases and arranged in the order of decreasing frequency were subarachnoid hemorrhage, cranial nerve changes, unilateral headache, generalized headache, convulsions, vertigo, facial pain, the migraine type of headache, and signs of hypopituitarism.

It is desirable to make the diagnosis of an intracranial aneurysm prior to rupture as 35 per cent of the patients in this series died on the first rupture and 21 per cent died because of recurrent hemorrhages.

It is necessary to know the tolerance of the affected hemisphere to reduction in the blood supply. This can be found by temporarily occluding the internal carotid artery by digital compression. If an irritable carotid sinus is present the compression should be on the common carotid artery well below the bifurcation.

If the aneurysm is large enough, plain roentgenograms of the skull may show a unilateral enlargement of the sella turcica, elevation or thinning of one of the anterior clinoids, or thinning of the lateral margin of the optic foramen. At times, calcification within the aneurysm may be seen.

In this series of cases thorotrast was originally used as the contrast media, but diodrast is now used more frequently. Since 75 per cent of intracranial aneurysms involve the anterior two thirds of the circle of Willis this portion should be visualized first. If the closed method is used the posterior third can be visualized by occlusion of the internal and external carotid arteries during injection of the common carotid. The Lahey Clinic uses the closed method more routinely than the open method because often both sides have to be investigated and the closed method is a minor procedure compared to exposure of both the carotid arteries.

The closed method is carried out with the patient on his back with his head in the horizontal position alongside of an upright automatic Bucky diaphragm. An 18 gauge needle, 2 inches long and attached by

means of a two way petcock to a 20 c.c. Luer-Lok syringe, is introduced into the common carotid artery 1 or 2 cm caudad to the bifurcation. When the needle is in the artery some citrate solution already in the syringe is injected to prevent clotting of the blood in the syringe and needle, and then a syringe containing the diodrast is attached to the needle. The needle is directed laterally and downward so that the contrast media enters the internal carotid artery and not the external. While 15 c.c. of diodrast are being injected as rapidly as possible, the first exposure is made, the stereoshift is carried out, and a second exposure is taken. The author finds that this lateral stereoview is more valuable than a single lateral and a single anteroposterior view. The entire procedure requires great co-operation between the neurosurgeon and the radiologist.

JOHN W. HOPE, M.D.

Place of Deep External X-Ray Irradiation in the Treatment of Carcinoma of the Cervix by Long Element Needles
 GEORGE W. WATERMAN and
 WILLIAM A. REID *Radiology*, 1949, 52: 34.

The authors review their experience over a 10 year period (from 1933 to 1942) at the Rhode Island Hospital, Providence, Rhode Island, with the treatment of 347 cases of cancer of the cervix. One hundred and thirteen patients were treated primarily with radium needles alone, and 234 were treated primarily with radium needles and x-rays. The 5 year survival in this group was 15.4, or 44.4 per cent.

In order to give a more accurate picture, comparisons between the two groups are made on the basis of similar clinical stages. The Schmitz classification was used. Stages 1 and 2 represent the operable or favorable group and stages 3 and 4 the inoperable and still purely radiological group.

In reviewing the statistics of the cases it is noted that 56 patients in stages 1 and 2 who were treated by interstitial radiation alone showed a 5 year salvage of 45, or 80.4 per cent. On the other hand, the salvage for a similar group of 77 operable patients treated by radium needles and x-ray irradiation was only 64.9 per cent, a difference of 15.5 per cent in favor of radium alone. In the inoperable or unfavorable group (stages 3 and 4) there was a 22.8 per cent survival for the 57 patients treated with needles alone and a 29.3 per cent survival for 157 patients receiving x-ray irradiation in addition to the radium.

The incidence of complications was markedly higher in the operable cases when x-rays were used with needles, being 22.1 per cent or more than twice that with needles alone (10.7%). In the inoperable group the gross incidence of complications did not vary so widely. The group treated with needles and x-rays showed fewer complications—12.1 per cent as compared with 14 per cent when radium alone was used.

The incidence of fistula in patients treated with needles alone was 3 in 113, or 2.7 per cent, occurring in patients with carcinoma of stages 3 and 4. In the patients treated with needles and x-rays the fistula

incidence was 13 in 234, or 5.6 per cent. Five of these had carcinoma in stage 1 or 2, an incidence of 6.9 per cent for these two stages. In 94 patients to whom x-ray therapy was given less than 1 month before or after radium treatment, the incidence of complications was 22.3 per cent as compared with a gross incidence of 12.3 per cent for all stages when radium was used alone. By increasing the interval to at least 8 weeks between the radium and x-ray therapy the complications were cut down. The use of a 4 cm. lead strip over the lower abdomen above the symphysis was found to reduce the x-ray overdosage to the paracervical area, which was considered responsible for some of the complications.

The x-ray factors used were 200 kv., 20 ma., target-skin distance 50 cm., filter 0.4 mm., of tin (Thoreaus). Two large fields (one anterior and one posterior) were used. The method of radium treatment consisted of using 2 and 3 mgm. needles (a total from 24 to 30 mgm. in early cases, and rarely more than 50 mgm. in late cases), and a 20 mgm. cervico-uterine application, gamma radiation, 0.5 mm. of platinum filter, and a long interval of 168 hours or 7 days.

The authors conclude that in making use of long paracervical and parametrial element needles, great caution should be used in stages 1 and 2 when x-ray radiation is given externally. The cervix and paracervical triangle should be shielded as much as possible. An interval of from 9 to 12 weeks after treatment with radium before use of x-rays gives the best results with regard to freedom from complications. In badly infected and more advanced cases preliminary x-ray therapy has its proper place.

RADIUM

Probable Trends in the Irradiation Treatment of Carcinoma of the Cervix Uteri with the Improved Expanding Type of Radium Applicator
 EDWIN C. ERNST *Radiology*, 1949, 52: 46.

The author presents an improved type of radium applicator to meet the problem of obtaining a greater degree of radiation effectiveness in the potential metastatic parametrial pelvic field, in the treatment of carcinoma of the cervix uteri. More effective and uniform irradiation is obtained by use of this radium applicator. The uniform spacing of multiple equal radium sources is not disturbed when the lateral capsules of this particular type of radium holder are expanded to pre-established fixed positions, irrespective of the anatomical size and shape of the vaginal vault or the extent of the malignancy.

The applicator is so constructed that in the closed position the transverse diameter measures less than 3.0 cm., which makes for ease of introduction. The lateral colpostats are expanded mechanically by use of a rotating knob on a handle which is detached after introduction, and the applicator is packed and fixed in the desired expanded position. The cervical stem of the applicator, when three longitudinal capsules are employed, is approximately 7 cm. in

length. The distal stem can be removed if less length is desired. The two lateral colpostats can be expanded to the desired extent to contact the parametrial fields effectively. When the lateral transverse diameter measures only 5 cm, four or five radium capsules can be comfortably introduced. The 6.5 cm vault occasionally will accommodate six radium capsules. If the cervical canal is occluded, the cervical stem of the applicator may be removed. The roof and floor of the vaginal vault are packed with a single narrow gauze strip to maintain constant pressure on the radium holder. Roentgenograms taken after insertion of the applicator are of value to determine its position. In a contracted vaginal vault, only four or five capsules can be accommodated. The radium compartments of the applicator are for either one, two, or three 10 mgm needles.

Injury to the bladder and the rectum are minimized due to the design and mechanical features of the lead-filled ends of the vertical radium capsules. The radiation distribution has been evaluated for both the single capsule and the total radium intensity effects of the applicator upon photographic films by substituting a presdwood phantom for the soft tissues of the pelvis in order to determine that all the surrounding pelvic fields were uniformly and effectively irradiated.

The studies show an improved field of radiation around the present applicator which employs nine equally spaced radium sources. Unequal distribution of the radium sources within the cancer fields or the surrounding normal structures of the pelvis creates a clinicobiological irradiation hazard.

From the standpoint of clinical research, this method facilitates the more accurate comparison and

clinical evaluation of the relative effectiveness of various radium application in relation to the time and intensity factors of the total radium dose.

The Lethal Dose of Total Body X-Ray Irradiation in Swine JOHN L. TULLIS, CARL F. TESSMER, EUGENE P. CRONKIRE and F. W. CHAMBERS, JR.
Radiology, 1949, 52: 396

The effect of ionizing irradiation on swine was studied in an effort to better interpret the data obtained in the Bikini tests. Experiments on swine are of value because of a closer similarity to the radiosensitivity of man.

A one million volt unit operating at 3 ma (angle beam of 95 to 135°), 1 meter distance, and at 30 roentgens per minute, was used. Two lateral fields were given to each swine over a 45 minute period, the dosages varying from 200 to 600 roentgens in air. All swine were sexually mature, from 12 to 15 months old, there were 4 females and 4 males in each group.

Results within a period of 30 days following irradiation showed no difference as far as sex was concerned. Of the 8 animals receiving 200 roentgens, one (12.5%) died, of the 8 animals receiving 300 roentgens, 5 (62.5%) died, 7 of 8 (87.5%) that received 400 roentgens, died, and 8 of 8 (100%) that received 600 roentgens, died.

The results of these studies show that in spite of some differences in the ionizing components of the atomic bomb and one million volts, the biologic responses are similar and comparable.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Venous Pressure in Relation to Blood Volume in Man MARTIN E. ANDERSON, JR., and JOHN S. LUNDY *Anesthesiology*, 1949, 10 145

In the state of shock, the effective volume of the circulating blood is reduced. This may be due to actual loss of blood volume (as whole blood or plasma), to pooling of the blood in the venous reservoirs of the body, or to other factors such as heart failure. When the effective blood volume of the body is reduced, there is a measurable drop in the blood pressure, often greater on the venous than on the arterial side. With recovery from shock, the arterial and venous pressures approach more nearly normal limits.

It is an easy matter to make frequent observations of the arterial blood pressure, and much reliance is placed on these determinations in evaluating the efficacy of management of the patient in shock. It is unfortunate that a record of the venous pressure is not so easy to obtain, for the venous pressure also reflects the disparity between the capacity of the circulatory bed and the volume of the circulating fluid within the vascular system. A drop in the venous pressure may be an earlier warning of impending shock than is a fall in the arterial pressure.

Since it has been found that the effective blood volume drops in shock and is restored toward normal as this condition is overcome by replacement of the lost fluid, two series of observations were made to determine whether measurement of the relative venous pressure could be used as a method of measuring this change. In the first series, the change in venous pressure was measured on 25 human donors after removal of 500 c.c. of blood. In the second series, the change in venous pressure was determined in 20 patients after the infusion of 500 c.c. of whole blood. As a corollary to this latter series of observations, the change in venous pressure was determined in 20 postoperative patients after infusion of varying amounts of saline solution at a constant rate.

The authors found that it is a simple matter to obtain venous pressure determinations when intravenous tubing is in progress by attaching to the intravenous tubing a venous pressure manometer with its saline reservoir. It is believed that determinations of venous pressure accurately reflect changes in the total blood volume which are more difficult to discover by other methods. The procedure has a limited usefulness in guiding the intravenous therapy of patients in surgical shock, and might also be of value when solutions are to be administered intravenously to patients with a variety of conditions in which further increase in venous pressure is to be avoided, such as congestive heart failure, constrictive pericarditis, ascites, and Banti's disease.

Rapid withdrawal of 500 c.c. of blood from each of 25 donors produced a fall of venous pressure from an average resting value of 112 mm. of saline solution to 77 mm. Transfusion of 500 c.c. of whole blood into 20 patients produced a rise of venous pressure from 64 mm. to 92 mm. Infusion of physiologic saline solution did not restore the venous or arterial pressure to the preoperative level.

The Common Nonvascular Nevi and Their Treatment A. J. DELARIO *Am J Surg*, 1949, 77 53

The commonness of the various forms of pigmented and nonpigmented nevi is established, and a classification of these many and varied lesions is given. Nevi are defined as skin lesions containing neval cells with or without pigment, and with or without hair. Their origin is probably from nerve tissue, due to their ability, through the neval cells, to produce pigment, and the fact that the production of melanin is under the control of the pituitary, adrenal, and gonads—other derivatives of nervous tissue.

Differentiation between pigmented nevi, and other similar lesions such as seborrheic warts and senile keratoses, may be made on the fact that when superficial layers are removed the base is still easily identifiable. Further differentiation may be made on degeneration in which other lesions form basal or squamous cell carcinomas, whereas pigmented nevi form melanomas.

Malignant degeneration must be suspected when changes in size, shape, or coloration take place. Most common are (1) the small deeply pigmented nevi, with or without hairs, which occur especially on the extremities, and (2) the soft, smooth, slightly elevated, moderately pigmented mole, which is not common on the extremities. From 30 to 60 per cent of malignant melanomas arise from recognizable pigmented nevi, fewer, however, arise from the hairy types. They may occur at any age from 6 months on, however, the average age of onset is 50 years. Usually, they do not metastasize before puberty. They occur anywhere—most frequently on the head, neck, foot, and trunk.

Prophylaxis consists of removal. Criteria have been established to include those that are darkly pigmented, those appearing suddenly late in life, those subjected to trauma and irritation, those which show increased pigmentation, and those that show signs of hemorrhage.

Methods of treating nevi vary from simple excision or electrocautery to multiple-stage resection of the larger types with removal of the proximal lymphatic chains. In some instances in which disfigurement would be excessive, lesions were irradiated in the hope that a few of them might be radiosensitive. The cure rate in presented case studies has not been higher than 33 per cent, including all types of therapy.

ARMAND D. ALBRECHT, M.D.

Studies in the Virulence of *Clostridium Welchii*
W A ALTEMEIER and W L FURSTE *Surgery*,
1949, 25 12

It has long been recognized that certain types of wounds, such as extensive lacerations, compound fractures, or crushing injuries are particularly prone to develop gas gangrene. In World War I, Callender and Coupal found the incidence of gas gangrene to be from five to six times higher in compound fractures than in soft tissue wounds. Gas gangrene is of multiple bacterial etiology, a great variety of gas-producing anaerobic bacteria have been found associated with this condition, although the fact remains that the *Clostridium welchii* is the principal cause of gas gangrene and was present either alone or in association with other gas-producing anaerobes in from 56 to 100 per cent of the patients who were studied.

Since the *Clostridium welchii* is found in all human environment with widespread distribution in the soil, sewage, the hair of domestic animals, dust, skin, and vaginal tract, contamination of a considerable proportion of the open wounds is almost inevitable, and the average incidence of contamination of 3,027 collected wounds was 15.7 per cent. Nevertheless, clinical gas gangrene is relatively infrequent, with an average incidence as an infectious complication of open wounds of 1.62 per cent. Clinically, when a muscle is deprived of its blood supply for 6 or 8 hours, it usually dies, and hence it becomes a more suitable site for *Clostridium* development. This explains the gas gangrene which sometimes takes place following thrombosis or embolism.

A study to measure accurately the effect of crushed muscle and dirt on the development of gas gangrene, and, if possible, to evaluate the importance of these two factors was undertaken. Measured doses of the *Clostridium welchii* of high virulence were injected into the thigh muscles of guinea pigs which were (a) normal, (b) traumatized by crushing 5 times with a Kocher clamp, and lacerated by a twisting clamp, and (c) traumatized as before with the addition of 1 c.c. of an autoclave and a finely divided mixture of soil and cinders in the wound just before closure.

It was found that 1,000 times fewer bacteria were required to produce fatal gas gangrene in lacerated muscle than in healthy muscle, and that 1,000,000 times fewer bacteria were required to produce fatal gas gangrene in the presence of devitalized muscle and dirt than when injections were made directly into healthy muscle.

The factors governing the virulence of the same strain of *Clostridium welchii* are not well known. It is clear that the potential virulence of the same strain may vary considerably, even under apparently identical conditions (passage through pancreatic digest medium enhances the virulence of the strain of *Clostridia* used in these experiments, as does weekly passage through pigeons).

FRANK B. QUEEN, M.D.

Blastomycosis Infestation with the *Paracoccidioides Brasiliensis* *Anatomopathologic Study and Fluorescent Coloration of the Parasite* (Blastomycosis por paracoccidioides brasiliensis estudio anatomopatológico y coloración fluorescente del parásito) JUAN C. RADICE and SALOMÓN KAPLAN *Rev. As. Méd. Argent.*, 1949, 63 61

The cadaver turned over to the authors for study presented numerous lesions of the mouth, trachea, bronchial tree and lungs, right suprarenal gland, and both lobes of the cerebrum. There were suggestive lesions palpable in other organs (spleen and pancreas), however, those cited were the only ones subjected to extensive study. All the lesions examined were either in the form of ulcerations, nodular infiltrations, or abscesses, and all were typical of the reported lesions of blastomycosis, that is, they were not easy to distinguish from those of tuberculosis.

For more definite and more frequent recognition of the parasite the authors resorted to a special method of treatment of the tissues. The tissues were fixed in alcohol, cut into microscopic sections (7 microns) by the usual paraffin fixation method, then the paraffin was removed with xylol, and the section was rehydrated with decreasing strengths of alcohol and treated with phosphomolybdic acid (1 per cent) for a half hour and then stained with primulin (1 to 5,000) for 24 hours. The tissue sections were then dehydrated a second time, cleared with xylol, and mounted in Canada balsam. The preparation was then exposed to the rays of the sun or to rather long waves (3,600 U.A.) of ultraviolet light. When rendered fluorescent the sections were examined by means of special filters and a special fluorescent microscope.

The *Paracoccidioides brasiliensis* is identifiable by its fluorescent effects. It has a secondary fluorescence, colorless, brilliant, and luminous. The parasites were found in the giant cells in the pulmonary tissues, in the suprarenal gland tissues, and in the tissues of the brain. In each case, and especially in the brain tissues, it was found that by this method of fluorescent staining the limits of the lesions could be more accurately determined, the parasite could be more surely recognized, and that the organisms could be found much more frequently than with ordinary hematoxylin-eosin staining.

JOHN W. BRENNAN, M.D.

Studies on the Self-Disinfecting Power of the Skin A. HELLAT *Ann. med. exp. biol. fenn.*, 1948, 17 Supp. 8

In the present study, the author seeks to explore and appraise the problem of self-disinfection of the skin. Hellat attempts to determine whether the skin possesses self-disinfecting powers. If so, he wishes to determine the nature of this power if it is detectable. Finally, he attempts to determine whether the self-disinfecting mechanisms of the skin may account for the type of microflora found upon normal skin.

In this investigation, various test organisms were used and the tests were conducted in the Second

Surgical Clinic of the University of Helsinki All tests were performed upon normal healthy skin which had been kept unwashed for at least 3 days The skin was not shaved at any time

Some 13 experiments were performed with use of the various test media upon the skin of the forearm, palm, and sole of the foot, as well as in the armpit As a result of these experiments it was shown that the survival of bacteria differs greatly even under favorable conditions Further, the author is certain that no highly active bactericidal or inhibitory agent was found in the skin, with the possible exception of lysozyme

BENJAMIN GOLDMAN, M D

Lack of Extractable Carcinogens in the Skin of Patients with Multiple Precancerous Keratoses of Actinic Origin FREDERIC E MOHS *Cancer Res*, 1948, 8 371

The possibility that the skin of patients with multiple precancerous keratoses of actinic origin might contain extractable carcinogenic chemicals was considered and investigated Twelve patients with such lesions, and who previously had carcinoma, were selected for study All were instructed to wash one side of the face daily with benzene on gauze pads, saving the pads for extraction This material was then extracted and concentrated
